The ookinete traverses the midgut wall by passing through epithelial cells and comes to rest adjacent to the basal lamina. Here it begins to transform into an oocyst. From the 6th day onward, the oocyst undergoes cell division that eventually results in the formation of about 8000 daughter cells called sporozoites. By day 12, they are released into the hemocele of the mosquito and migrate to the salivary glands. In the salivary glands, they become infectious for humans and are released into the human host when the mosquito feeds.

### Differences Between *P. falciparum* and Its Life Cycle and the Other Parasites That Cause Human Malaria

These differences are outlined in Table 90-1. One of the most important differences is that *P. vivax* and *P. ovale* can have prolonged (up to 3 years) liver stages. Some populations of *P. vivax* and *P. ovale* sporozoites invade hepatocytes, arrest further development, becoming hypnozoites (sleeping forms),<sup>22,23</sup> and then activate and initiate replication and full development a month to several years after the primary infection. When a patient who was appropriately treated for an asexual erythrocytic stage *P. vivax* or *P. ovale* infection and had elimination of clinical manifestations of the disease and all parasites from the bloodstream (clinical cure) has a recurrent case of malaria caused by development of hypnozoites, the patient is considered to have a relapse (see Box 90-1). In addition to secondary attacks caused by hypnozoites, some isolates of *P. vivax*, especially those acquired in temperate regions of the world (e.g., Korea, China) cause delayed primary infections owing to persistence in the liver that may occur up to 1 year after inoculation of sporozoites by mosquitoes. These parasites are called *P. vivax* var *hibernans*. This phenomenon of delayed primary attacks has been reported with *P. falciparum*<sup>24</sup> but is much less common than with *P. vivax*.

*P. vivax* differs from the other three parasites in that *P. vivax* merozoites cannot invade erythrocytes that lack the Duffy blood group antigen.<sup>25</sup> Duffy protein on the erythrocyte membrane is a receptor for a protein ligand on the merozoite surface called the Duffy binding protein or ligand (DBL).<sup>26</sup>

*P. falciparum*, *P. vivax*, and *P. ovale* take approximately 48 hours to complete the asexual erythrocytic stage of their life cycle (invasion, development, rupture, and reinvasion), and are called tertian (recurring every 3rd day) malarias. *P. malaria* has an approximately 72 hour cycle and is called quartan (recurring every 4th day) malaria.

### Genomics of *P. falciparum*

The genomic sequence of chromosome 2 of *P. falciparum* was published in 1998,<sup>27</sup> and the entire genomic sequence of the 3D7 clone, which has been maintained in culture for two decades, was published in 2002.<sup>28</sup> The *P. vivax* genome has been partially sequenced, and while some results are available on the Internet, the results have not yet been published. Active genome projects involving over a half-dozen other rodent and simian *Plasmodium* species, as well as a *P. falciparum* isolate obtained directly from a patient, are under way. Since there is substantial evolutionary conservation among *Plasmodium* species,<sup>29</sup> a great deal can be inferred through comparative genomics.<sup>30</sup>

The *P. falciparum* genome is approximately 23 Mb in size and encodes about 5300 genes on 14 chromosomes. Fifty-four percent of the genes contain introns. On average, the coding regions of *P. falciparum* genes are longer than in other sequenced eukaryotes such as *Schizosaccharomyces pombe* (2.3 kb vs 1.4kb). The reason for this increased gene length is unknown. Fully 60% of the encoded proteins have little or no similarity to proteins in other organisms and are of unknown function. The proportion of genes encoding these so-called hypothetical proteins is higher in *P. falciparum* than in other sequenced organisms, which is probably a reflection of the greater evolutionary distance between *Plasmodium* and other well-studied eukaryotes.

Analysis of the predicted proteome provides an overview of metabolism and transport in malaria parasites.<sup>31,32</sup> A number of features of parasite metabolism remain unclear because of the absence of some enzymes or enzyme subunits and because the predicted subcellular localization of some enzymes differs from the known localization of the enzymes in other organisms, making it difficult to reconstruct the metabolism of the parasite with certainty. A remarkable feature of this parasite is its relative lack of transcription factors, implying that the parasite relies to a large extent on post-transcriptional control of gene function.

*P. falciparum* appears to have greatly reduced capacities for metabolism and for the transport of organic nutrients and ions as compared with other free-living organisms. Only 14% of the proteins encode enzymes. This is a much lower proportion than in other eukaryotes. Similarly, the *P. falciparum* genome encodes a smaller repertoire of membrane transporters in comparison with other free-living eukaryotic microbes such as *Saccharomyces cerevisiae*. The *P. falciparum* genome encodes enzymes for the complete glycolytic pathway from glucose-6 phosphate to pyruvate, and for the conversion of pyruvate to lactate. All enzymes of the tricarboxylic acid (TCA) cycle have been identified, but the function of the TCA cycle is unclear.

Other unusual features of *P. falciparum* metabolism that can be inferred from the genome sequence are the absence of gluconeogenesis and the lack of any enzymes for the biosynthesis of amino acids, apart from enzymes required for amino acid interconversions. The lack of amino acid biosynthetic pathways, and the apparent absence of clear homologs of known amino acid transporters, emphasizes the parasite's dependence on the host for amino acids, at least in the erythrocytic stages in which amino acids are obtained by the digestion of hemoglobin in the food vacuole. Overall, the metabolic and transport capabilities of *Plasmodium* are less than those of other free-living organisms, which may be a reflection of its parasitic lifestyle.

A clear difference between the genome of *P. falciparum* and other sequenced eukaryotes is the abundance of genes in the malaria parasite that are involved in immune evasion and other host-parasite interactions (3.9% and 1.3%, respectively). The 3D7 genome contains 59 *var* genes that encode highly polymorphic proteins known as *P. falciparum* erythrocyte membrane protein 1 (PfEMP1).<sup>19–21</sup> These proteins are expressed on the surface of infected red blood cells, mediate cytoadherence of the infected cells to host capillary endothelium, and cause sequestration of the infected cells in many organs, including the brain. The PfEMP1 proteins are thought to be the targets of protective antibody responses, but

transcriptional switching between different *var* genes provides for antigenic variation and the evasion of the host immune response. The *rif* genes, of which there are 149 in the 3D7 genome, encode proteins called rifins. A third group of proteins called STEVORs (28 in the 3D7 genome) are similar in sequence to the rifins and so far, like the rifins, have no known function. Members of the PFEMP1, rifin, and STEVOR families exhibit extensive sequence diversity, and the genes encoding these proteins occur in clusters, most of which are located in subtelomeric regions in association with several kinds of repetitive sequences. The repetitive sequences are thought to facilitate recombination between different alleles of these highly polymorphic proteins and contribute to the generation of antigen diversity.

The availability of the genome sequence of *P. falciparum* has paved the way for detailed analyses of parasite biology. Technologies such as DNA microarrays<sup>33,34</sup> and proteomics<sup>31,32</sup> have provided means to assess how the parasite responds to its environment and how it functions as an organism requiring two such different hosts as humans and mosquitoes, and they may provide clues to developing new interventions against the parasite and the disease it causes.

## EPIDEMIOLOGY

Malaria transmission occurs in most of Africa south of the Sahara desert; in many areas of the Indian subcontinent, Southeast Asia, and Oceania; in Central America, Haiti and the Dominican Republic; and in the Amazon basin of Brazil and contiguous countries in South America. The global distribution and prevalence of malaria infection have not changed appreciably for the past few decades. While malaria infection is widely distributed, the intensity of transmission of *Plasmodium* is greatest in Africa, where in excess of 70% of new infections globally are estimated to occur annually.

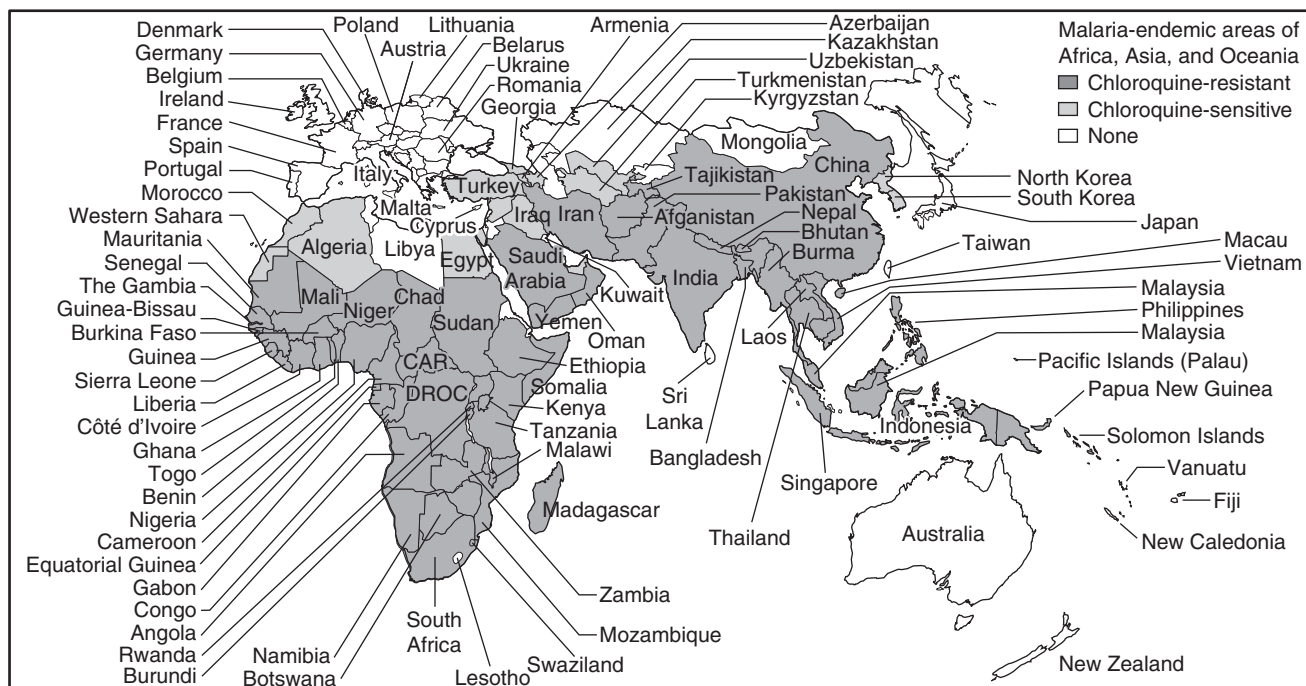

Malaria infection with the four *Plasmodium* spp that naturally infect humans is characterized by persistence of the blood stage of parasites for intervals of from months to life-long, without therapy. Consequently, in areas, notably Africa, it is difficult to characterize the incidence (of new infections) of malaria since the prevalence of infection is persistently high. It has been estimated that in the range of 300 to 800 million new malaria infections occur globally each year<sup>1</sup>; however, this figure is highly imprecise, particularly in areas of high levels of transmission in Africa.<sup>35</sup>

The major determinants of the epidemiology of malaria infection and disease relate to the *Plasmodium* spp, the transmission intensity, innate and acquired resistance of the human host, and access to and efficacy of control measures. In addition, the immunocompromised states associated with pregnancy and infection with human immunodeficiency virus (HIV) affect the epidemiology of malaria.

## *Plasmodium* Species

The species that causes the greatest illness and death in humans, *P. falciparum*, is the predominant infection in Africa south of the Sahara, in the Amazon basin and Haiti, and many areas of Asia and Oceania. *P. vivax* is widely distributed in the Americas and Asia, and only in very circumscribed areas of Africa. The two less prevalent species, *P. malaria* and *P. ovale*, are transmitted in some areas of Africa

Chloroquine sensitive and resistant *P. falciparum* in Africa, Asia, and Oceania (Courtesy of Dr. M. Parise: Health Information for International Travel. Atlanta, Centers for Disease Control and Prevention, 2005–2006, in press.)

and the Amazon basin and sporadically in other parts of the world such as Oceania and Southeast Asia. As a consequence of this distribution, most illness and death attributable to malaria occurs in Africa, Asia, and the Amazon region of Brazil.

Chloroquine sensitive and resistant *P. falciparum* in Central and South America and the Caribbean (Courtesy of Dr. M. Parise: Health Information for International Travel. Atlanta, Centers for Disease Control and Prevention, 2005–2006, in press.)

### Transmission Intensity

*Plasmodium* parasites are transmitted to humans by female mosquitoes of the *Anopheles* genus. Worldwide approximately 40 anopheline species have been documented to transmit parasites to humans. These species vary remarkably in their capacity to transmit *Plasmodium* to humans. This variability relates to basic habits, including tendency to seek out humans for a blood meal, types of water sources preferred for laying eggs, and predilection for entering human dwellings, as well as basic biologic capacity to support the development of human *Plasmodia* to development of mature infection that can be transmitted during the taking of a blood meal. Anopheline species with the greatest competence to transmit *Plasmodium* are found in the Amazon (*Anopheles darlingi*) and Africa (the species complex of *An. gambiae*).

Several identifiable factors characterize the capacity of *Anopheles* mosquitoes to transmit *Plasmodium*. The adult female mosquito can survive under ideal conditions up to 50 to 60 days. Practically, however, female anophelines survive on the average of 20 to 25 days, and consequently must be infected by malaria parasites in their early blood meals, taken every 3 to 4 days. Maturation of the parasites ingested with the blood meal requires 8 to 12 days before the mosquito has infective sporozoites in her salivary glands. Mathematical modeling of malaria transmission by MacDonald<sup>36</sup> and others incorporates a measure of mosquito density in a defined setting and the probability that an *Anopheles* will feed on a human during a day.

The epidemiologic measure of transmission intensity is the entomologic inoculation rate (EIR), which depends on the proportion of female anophelines with salivary glands infected with *Plasmodium* and the number of potentially infected *Anopheles* mosquitoes feeding on a person in a unit of time (day or year). There is a wide range of documented

EIRs by both time and area of the world, and even within regions of a country. In the areas of Africa with the most intense annual transmission, EIRs can reach three infected bites per day at the peak of transmission for short periods. By contrast, in most malaria endemic regions of the Americas and Asia, annual EIRs range from less than 1 up to 10 infected bites annually.

Mathematical models of malaria transmission have constructed several composite statistics to quantitate the risk of malaria transmission in defined epidemiologic settings. Vectorial capacity incorporates estimates of mosquito density and human biting rate along with daily survival (longevity) of anopheline mosquitoes to estimate the overall either receptivity or intensity of malaria parasite transmission in a defined setting. The estimation of vectorial capacity can be used to compare transmission risk in time and space, and in principle also to monitor the effect of measures used to control malaria transmission.

Black<sup>37</sup> developed the concept of the reproductive rate for malaria transmission that estimates the number of secondary cases of malaria that are predicted from an infected human in a population susceptible to malaria infection. A reproductive rate greater than 1.0 predicts sustaining malaria transmission in a population. Efforts to interrupt transmission must maintain the reproductive rate less than 1.0. Most of these mathematical models were developed and refined during the last century in conjunction with malaria eradication attempts and have not been refined to address malaria transmission dynamics in highly immune populations as encountered in Africa.

In Africa, transmission intensity has a major effect on the clinical manifestations of severe disease and the age at which they are encountered. For example in areas with extremely high entomologic inoculation rates (100 to 300 potentially infective bites/year) and long transmission seasons, most severe disease and malaria-associated deaths occur in infants and young children, and the primary cause of malaria-associated death is severe anemia. In areas with much less intense transmission (10 to 40 potentially infective bites/year) and more limited transmission periods, most cases of severe malaria and deaths occur in older children (e.g., 3 to 7 years of age), and cerebral malaria is responsible for a high percentage of the deaths.

### Innate and Acquired Resistance

Protection from malaria can be expressed as decreased risk of being infected (developing blood-stage parasitemia) or decreased risk of developing higher density parasitemia and clinical illness due to the parasitemia (clinical immunity). This protection is mediated by innate mechanisms and by acquired adaptive immune responses. In settings of natural transmission, it has been demonstrated that humans do not acquire persisting protection from being infected by mosquito transmission but do develop immune-mediated protection against parasites and disease. It is presumed that in the field the natural variability of the *Plasmodium* parasite (antigenic variation) is the major factor responsible for persisting susceptibility to infection even after lifelong exposure.

#### Innate Resistance

It has often been stated that malaria has had more impact on the human genome than any other infectious agent. In settings where humans are exposed to high levels of malaria

transmission, it has been documented that genetically determined traits are selected for over generations that mediate protection against either infection or the risk of clinical or severe malaria illness.

A well-characterized protective mutation is the Duffy factor, a minor erythrocyte surface antigen that, in the homozygous recessive state, is associated with complete protection against *P. vivax* infection.<sup>25</sup> The Duffy antigen is sterically associated with the protein required for attachment and penetration of *P. vivax* merozoites into red blood cells. The homozygous Duffy configuration is uniform in African blacks, and variable among blacks of African origin, and vivax infection does not occur in homozygous recessive individuals.

The sickle cell mutation in human hemoglobin is a balanced polymorphism that has been selected for in areas of intense *P. falciparum*, mainly in Africa. In the heterozygous state, the sickle trait affords protection against the development of higher density, life-threatening parasitemia, probably because the variant hemoglobin is a poor substrate for digestion by the parasite and because the infected cells are more easily subject to mechanical damage in the circulation.<sup>38,39</sup> Some studies have shown that the incidence rate of cerebral malaria is reduced by 90% in children with sickle cell trait as compared with their peers.<sup>45</sup> There is evidence that a number of other polymorphisms including hemoglobinopathies and erythrocyte membrane variants have evolved and afford a survival advantage to affected individuals. For example, recent studies in West Africa have demonstrated that hemoglobin (Hb) C affords protection against a range of malaria illness manifestations.<sup>40</sup> Other erythrocyte disorders associated with an advantage to the host include HbE, HbF, alpha- and beta-thalassemia, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and red cell cytoskeleton abnormalities such as ovalocytosis. These and other red cell abnormalities effecting infection with *Plasmodium* spp parasites have been recently summarized.<sup>38</sup>

### Reduction of Morbidity and Mortality of Malaria by Adaptive Human Immune Responses

Acquired or adaptive human immune responses occurring on the basis of an individual being exposed to infection with *Plasmodium* spp parasites can diminish the pathogenic effects of malaria parasites on the human host and also are implicated in the pathogenesis of disease. This section focuses on reduction in pathology. The role of host immune responses in pathogenesis is discussed in a subsequent section on pathogenesis.

In areas with the most intense *P. falciparum* transmission in sub-Saharan Africa, the role of host immune responses in ameliorating disease can be viewed as generally having three different stages during an individual's life.

**Neonatal Period and Early Infancy.** New infections, especially higher density parasitemias, and clinical manifestations of malaria are much less common in infants less than 6 months of age than in older infants and children.<sup>35,41</sup> Newborns have significant protection against high-density parasitemia for periods ranging to 6 months of age. This protective immunity is acquired passively across the placenta in utero, and presumably is primarily mediated by maternal antibodies.

**Late Infancy Through Childhood.** For several years infants and children are at great risk of developing repeated infections and life-threatening malaria. However, as they grow older the impact of malaria begins to diminish. Parasite densities are decreased as are the incidence rates of severe disease and *P. falciparum*-caused death. The rate at which clinical immunity is achieved varies directly with the intensity of transmission of *P. falciparum*. In areas with the highest entomologic inoculation rates, if a child survives to the age of 3, he or she may never again develop severe malaria or die of malaria. In areas with less intense transmission, this clinical immunity against severe disease may not occur until the age of 5, and in areas with even less intense transmission or seasonal transmission it may not occur until the age of 7 to 10.

The immunity is thought to be primarily mediated by antibodies against asexual erythrocytic stage parasites and their products. Antibodies against variant surface antigens such as PfEMP1<sup>19–21</sup> are thought to prevent sequestration of the infected erythrocytes in the microcirculation and thereby prevent microcirculatory obstruction and severe disease and allow for removal of infected erythrocytes in the spleen, reducing parasite burden. Antibodies against merozoite surface proteins are thought to either prevent invasion of erythrocytes or activate mononuclear cells to release cytokines, free oxygen radicals, and other biologically active substances that inhibit parasite development within erythrocytes, thereby reducing parasite burden. Antibodies against *P. falciparum* derived toxins such as glycosylphosphatidylinositol (GPI) are thought to inhibit the function of these toxins and limit the clinical manifestations of infection without necessarily affecting the parasites.<sup>42</sup>

**Late Childhood Onward.** Individuals become infected, probably at the same rate as young children, and may become ill from the infections. However, they have significantly lower concentrations of parasite-infected erythrocytes in the bloodstream, lower incidence rates of clinical disease, and essentially no severe disease or *P. falciparum*-induced death. The same immune mechanisms thought to contribute to the steady reduction of incidence of severe disease with increasing age in childhood are thought to mediate this antiparasite and antidisease immunity in older children, adolescents, and adults. It has been shown that administration of purified immunoglobulin from adults from areas highly endemic for *P. falciparum* in West Africa reduces *P. falciparum* infections by more than 95% in children in Africa and Thailand.<sup>43,44</sup> These studies prove that naturally acquired antibodies against asexual erythrocytic stages can have a dramatic effect on *P. falciparum* in infected people. It has been proposed that T cell responses against liver stages of the parasite life cycle may also play a significant role in naturally acquired protective immunity,<sup>45</sup> but the fact that adults and children<sup>46–49</sup> become reinfected at the same rate suggests that pre-erythrocytic stage immunity plays a minor role at best in acquired clinical immunity.

## Human Behavior and Environment

The interactions among humans, parasites, and mosquitoes in malaria transmission are complex. Human behavior not only influences individual risk of being infected, but human behavior and environmental impact can foster conditions that promote malaria transmission and risk. Human activity in clearing and settling land can create the conditions that

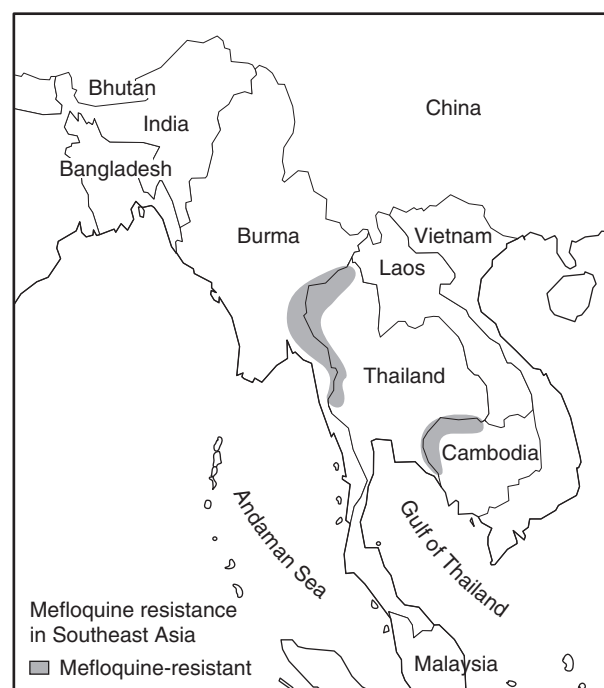

promote breeding of *Anopheles* mosquitoes. Excavation of earth, impounding of water, and the clearing of shade are factors promoting increased mosquito breeding in Africa and areas of the Americas. Housing construction (e.g., the presence of screening and windows) affects the ability of mosquitoes to enter dwellings at night when humans are indoors. Agriculture practices and certain occupations can increase the risk of infection, for example, in Southeast Asia when humans work in forest areas where malaria transmission occurs because those areas are the habitat of the predominant mosquito vector species.

## Use and Efficacy of Control Measures

The predominant measures to either prevent or treat malaria infection are the use of antimosquito interventions [insecticide-impregnated nets (ITNs), indoor residual insecticide spraying (IRS)] and the use of malaria drugs to either prevent or treat infection. The level of use of these interventions (coverage) as well as their efficacy has a major impact on the epidemiology of malaria as well as programmatic impact.

The efficacy of these interventions substantially alters individual risk of either infection or severe disease. For example, from large-scale trials of ITNs it can be estimated that there is up to a 74% reduction in malaria-associated malaria fevers requiring therapy when ITN coverage exceeds 70% to 80% at the community level.<sup>50</sup> Conversely, when the efficacy is compromised, for example, when drug resistance increases, significant increases in malaria infection risk and disease occur.<sup>51</sup>

Prompt treatment of malaria illness can substantially reduce the risk of progression to severe disease, and drug therapy can largely prevent the development of severe anemia

Mefloquine-resistant *P. falciparum* in Southeast Asia (Courtesy of Dr. M. Parise: Health Information for International Travel. Atlanta, Centers for Disease Control and Prevention, 2005–2006, in press.)

**Table 90-2** Distribution of Drug-Resistant *P. falciparum* Malaria

Region	Resistance Reported*				Comments
	CQ	SP	AQ	MQ	
Plasmodium falciparum infections					
Central America (Mexico, Belize, Guatemala, Honduras, EI Salvador, Nicaragua, Costa Rica, NW Panama)	N	N	N	N	Northwest of Panama Canal only
Carribean (Haiti and Dominican Republic only)	N	N	N	N	
South America (SE Panama, Columbia, Venezuela, Ecuador, Peru, Brazil, Bolivia)	Y	Y	Y	Y	Resistance to MQ and QN, although reported, is considered to occur infrequently
West Africa	Y	Y	N	N	SP resistance can be focally high
East Africa	Y	Y	Y	N	SP resistance is now high grade in many areas and amodiaquine resistance is increasing
Southern Africa	Y	Y	N	N	Resistance to SP high grade in KwaZulu Natal, South Africa, and variable elsewhere
Indian subcontinent	Y	Y	Y	N	Amodiaquine resistance in all areas, but SP still effective in some areas
Southeast Asia and Oceania	Y	Y	Y	Y	Border areas of Thailand, Cambodia, and Myanmar highest risk for multiple drug resistant infections; mefloquine resistance documented in eastern Myanmar, Thailand, Cambodia and southern Vietnam only
East Asia(China)	Y	Y	Y	N	Resistance greatest problem in southern China where bulk of falciparum transmitted

\*Reduced sensitivity to quinine occurs in parts of SE Asia and South America, but high level resistance is extremely unusual.

Adapted from Boland et al.

that is a prominent consequence of malaria infection in children and pregnant women in Africa. The emergence and geographic expansion of drug resistance (Table 90-2), mainly in *P. falciparum*, has compromised the effectiveness of prompt therapy to control malaria illness and risk of severe and chronic disease. In some areas of Southeast Asia and the Amazon basin, and increasingly in Africa, resistance to multiple drugs has resulted in ineffectiveness of most available and affordable drugs. The spread of chloroquine resistance across much of Africa south of the Sahara is the primary factor in the increase in incidence of severe pediatric anemia in many countries and in utilization of the already inadequate health care facilities.

### Immunocompromised States Including Pregnancy and HIV Infection

In settings where transmission of *P. falciparum* occurs, individuals with definable forms of immune compromise may be at increased risk of malaria. Two such conditions are pregnancy and HIV infection. In these settings adults generally will have experienced repeated malaria infections and acquired some immune protection prior to becoming pregnant or acquiring HIV infection. In neither condition is there complete reversal of the protection that has been acquired, although the immune mechanisms involved have not been defined.

*P. falciparum* infection during pregnancy produces a range of disease consequences. In settings of low intensity transmission, notably Southeast Asia and the Americas, pregnant women are at greater risk of high-density parasitemia

and severe disease compared with nonpregnant women having comparable prior malaria infection experience.<sup>52</sup>

In settings of more intense transmission, notably Africa, the accumulation of parasitized erythrocytes in the placenta has consequences for the pregnant woman and her fetus. Low birth weight (LBW) is the main fetal complication in all endemic areas, with maternal and fetal anemia also prominent consequences of maternal malaria infection in Africa. The risk of higher density parasitemia, anemia, and LBW is most pronounced in first and second “malaria-exposed” pregnancies.

Malaria infection has not proved to be an opportunistic infection (such as tuberculosis) in HIV-infected individuals in Africa. However, several clinically relevant interactions have been documented. Recently in southern Africa there have been reports that in adults living in areas with only sporadic malaria transmission, increased risk of severe malaria disease has been documented when HIV infection has progressed to AIDS. Further, in pregnant women, HIV infection does increase the risk of higher density parasitemia, and this would appear to be independent of parity.<sup>53</sup> Therapy for severe pediatric anemia, largely a result of malaria infection, has been associated with HIV transmission via blood transfusion in Africa, where blood is not uniformly screened for infectious agents.

### DISEASE

Malaria is a common cause of fever in tropical countries. The first symptoms of malaria are nonspecific: a lack of a sense of well-being, headache, fatigue, abdominal discomfort, and muscle aches are followed by fever. These symptoms are

similar to those of a minor viral illness. In some instances, headache, chest pain, abdominal pain, arthralgia, myalgia, or diarrhea may suggest another diagnosis. Nausea, vomiting, and orthostatic hypotension are common. Although headache may be severe in malaria, there is no neck stiffness or photophobia as in meningitis. Myalgia may be prominent, but it is not usually as severe as in dengue fever, and the muscles are not tender as in leptospirosis or typhus. The classic malarial paroxysms, in which fever spikes, chills, and rigors occur at regular intervals, are unusual and suggest infection with *P. vivax* or *P. ovale*. The fever is usually irregular at first (in falciparum malaria it may never become regular). Although febrile convulsions in childhood may occur with any of the malarias, generalized seizures are specifically associated with falciparum malaria and may herald the development of coma (cerebral malaria). Most patients with uncomplicated infections have few abnormal physical findings other than fever, malaise, mild anemia, and (in some cases) palpable splenomegaly. Anemia is common among young children living in areas with stable transmission, particularly where there is resistance to available antimalarials. Splenic enlargement is common among otherwise healthy individuals in malaria-endemic areas and reflects repeated infections (spleen rates [see Box 90-1] in healthy subjects are used to assess the intensity of malaria transmission); however, in nonimmune individuals with malaria, the spleen takes several days to become palpable. Slight enlargement of the liver is also common, particularly in young children. Mild jaundice frequently occurs in adults; it may develop in patients with otherwise uncomplicated falciparum malaria and usually resolves over 1 to 3 weeks. Petechial hemorrhages in the skin or mucous membranes—features of viral hemorrhagic fevers and leptospirosis—develop only rarely in severe falciparum malaria. There is no rash.

### Severe Falciparum Malaria

Appropriately treated, uncomplicated falciparum malaria carries a mortality rate of approximately 0.1%. However, once vital organ dysfunction occurs or the proportion of erythrocytes infected increases above 3%, mortality rises steeply.<sup>54</sup> In one large prospective study in a low transmission area of Thailand, patients with parasitemias greater than 4% but no signs of vital organ dysfunction had a mortality rate of 3%<sup>55</sup> (i.e., 30 times higher than that of other patients with uncomplicated malaria but 5 to 6 times lower than that of those with vital organ dysfunction). Clinical, clinical laboratory, and parasitologic findings associated with poor outcome are outlined in Box 90-2.<sup>54</sup> Coma is a characteristic and ominous feature of falciparum malaria (called cerebral malaria; Figs. 90-2 and 90-3) and, despite treatment, is associated with death rates around 20% among adults and 15% among children.<sup>54</sup> Lesser degrees of decreased level of consciousness including delirium, obtundation, and stupor should also be taken seriously. The onset may be gradual or sudden following a convulsion. Cerebral malaria is a diffuse symmetric encephalopathy; focal neurologic signs are unusual. There are no signs of meningeal irritation (see Fig. 90-2A). The eyes may be divergent, and a pout reflex is common, but other primitive reflexes are usually absent. The corneal reflexes are preserved except in deep coma. Muscle tone may be either increased

### Box 90-2 Clinical and Laboratory Findings That Predict a Poor Prognosis and Indicate That the Patient Should Be Hospitalized in an ICU<sup>54</sup>

#### Clinical

- Abnormal level of consciousness  
Cerebral malaria; Glasgow coma scale <11, Blantyre coma scale  $\leq 3$ <sup>107</sup>  
Deep coma has the worst prognosis, but delirium, obtundation, and stupor are associated with poor outcome
- Retinal hemorrhages
- Repeated seizures ( $\geq 3$  in 24 hours)
- Respiratory distress (rapid, deep labored, stertorous breathing)
- Heavy bleeding (unusual)
- Shock
- Jaundice with other vital organ dysfunction

#### Parasitologic

- >500,000 parasites/ $\mu$ L blood (~10%)
- >10,000 mature trophozoites and schizonts/ $\mu$ L blood (parasites with pigment)
- >20% parasites with visible pigment
- >5% neutrophils with malaria pigment

#### Laboratory

- Elevated serum creatinine (>250  $\mu$ mol/L)
- Acidosis (plasma bicarbonate <15 mmol/L)
- Hyperlactatemia (venous lactate >4 mmol/L)
- Hypoglycemia (blood glucose <2.2 mmol/L)
- Elevated liver enzymes ( $>3 \times$  normal)
- Elevated total bilirubin (>50  $\mu$ mol/L)
- Severe anemia (hematocrit <15%)
- Disseminated intravascular coagulation (with bleeding)

World Health Organization: Control of tropical diseases. Severe and complicated malaria. *Trans R Soc Trop Med Hyg* 84(Suppl 2):1–65.

or decreased. The tendon reflexes are variable, and the plantar reflexes may be flexor or extensor; the abdominal and cremasteric reflexes are absent. Flexor or extensor posturing may occur. Approximately 15% of patients have retinal hemorrhages on direct ophthalmoscopy (see Fig. 90-2B); with pupillary dilatation and indirect ophthalmoscopy, this figure increases to 30% to 40%. Other funduscopic abnormalities include discrete spots of retinal opacification (30% to 60%), papilledema (8% of children, rare in adults), cotton wool spots (>5%), and decoloration of a retinal vessel or segment of vessel (occasional cases). Convulsions, which are usually generalized and often repeated, occur in up to 50% of children with cerebral malaria. Covert seizure activity is common, particularly in children, and may manifest as repetitive tonic-clonic eye movements. Whereas adults rarely (<3%) suffer neurologic sequelae, approximately 15% of children surviving cerebral malaria—especially those with hypoglycemia, severe anemia, repeated seizures, and deep coma—have some residual neurologic deficit when they regain consciousness; hemiplegia, cerebral palsy, cortical blindness, deafness, and impaired cognition and learning—all of varying duration—have been reported.

Hypoglycemia is a common complication of severe malaria associated with a poor prognosis and is particularly problematic in children and pregnant women. Hypoglycemia in malaria results from a failure of hepatic gluconeogenesis and an increase in the consumption of glucose by both host and

A

B

C

**FIGURE 90-2** Clinical and gross pathologic findings in cerebral malaria. *A*, Child comatose with cerebral malaria with opisthotonus. *B*, Retinal hemorrhages (photomicrograph). *C*, Basal view of the brains of two children. On the left is a brain from a child with cerebral malaria. It is very congested and has a brown-grey color due to heavy hemosiderin (malaria) pigment deposition in the blood vessels. On the right is a normal brain, which is relatively pale. It has terminal meningeal congestion only. (*A*, Courtesy of © J. Crawley, Wellcome Trust International Health Image Collection; *B*, courtesy of N. White; *C*, courtesy of © S. B. Lucas, Wellcome Trust International Health Image Collection.)

parasite. Quinine and quinidine—drugs used commonly for the treatment of severe chloroquine-resistant malaria—are also powerful stimulants of pancreatic insulin secretion. Hyperinsulinemic hypoglycemia is a particular problem in pregnant women receiving quinine treatment. In severe disease, the clinical diagnosis of hypoglycemia is difficult: the

usual physical signs (sweating, gooseflesh, tachycardia) are absent, and the neurologic impairment caused by hypoglycemia cannot be distinguished from that caused by malaria.

Acidosis is a major feature of severe malaria and an important cause of death. Lactic acidosis is an important component and commonly coexists with hypoglycemia. In adults,

**FIGURE 90-3** Microscopic pathologic findings in cerebral malaria. *A*, Brain smear (Giemsa) showing sequestration of parasitized erythrocytes. *B* and *C*, Electron micrographs showing venules packed with parasitized erythrocytes; cross section (*B*), longitudinal section (*C*). *D*–*G*, Different parasite stages sequestered in different venules (reflecting asynchronous upregulation of endothelial adhesion receptors, mainly ICAM1). (From Silamut K, Phu NH, Whitty C, et al: A quantitative analysis of the microvascular sequestration of malaria parasites in the human brain. *Am J Pathol* 155:395–410, 1999. Courtesy of E. Ponpongratn and D. Ferguson.)

coexisting renal impairment often compounds the acidosis, and in children ketoacidosis may also contribute. Acidotic breathing, sometimes called respiratory distress, is a poor prognostic sign. It is often followed by circulatory failure refractory to volume expansion or inotropic drugs, or by respiratory arrest. The plasma concentrations of bicarbonate or lactate are the best biochemical prognosticators in severe malaria. The prognosis of severe acidosis is poor.

Adults with severe falciparum malaria, and sometimes vivax malaria, may develop noncardiogenic pulmonary edema even after several days of antimalarial therapy. This manifestation may also rarely develop in otherwise uncomplicated vivax malaria, where recovery is usual. The pathogenesis of this variant of the adult respiratory distress syndrome is unclear. The mortality rate in falciparum malaria is high. This condition can be aggravated by overly vigorous administration of intravenous fluid.

Mild hemolytic jaundice is common in malaria. Severe jaundice is associated with *P. falciparum* infection, is more common among adults than among children, and results from hemolysis, hepatocyte injury, and cholestasis. When accompanied by other vital organ dysfunction (often renal impairment), liver dysfunction carries a poor prognosis. Hepatic dysfunction contributes to hypoglycemia, lactic acidosis, and impaired drug metabolism. Occasional patients with falciparum malaria may develop deep jaundice (with hemolytic and cholestatic components) without evidence of other viral organ dysfunction.

Renal impairment is common among adults with severe falciparum malaria but very rare among young children. The pathogenesis of renal failure is unclear but may be related to erythrocyte sequestration interfering with renal microcirculatory flow and metabolism. This results in “acute tubular necrosis” although renal cortical necrosis never develops. Acute renal failure may occur simultaneously with other vital organ dysfunction, in which case the mortality is high, or may progress as other disease manifestations resolve. In survivors, urine flow resumes in a median of 4 days, and serum creatinine levels return to normal in a mean of 17 days. Early dialysis or hemofiltration considerably enhances the likelihood of a patient's survival, particularly in acute hypercatabolic renal failure.

Anemia is a prominent feature of malaria. Anemia can develop rapidly, and transfusion is often required. In many areas of Africa, children may develop severe anemia resulting from both shortened red cell survival and masked dyserythropoiesis, as a consequence of repeated malarial infections. Anemia is a common consequence of antimalarial drug resistance, which results in repeated or continued infection.

Slight coagulation abnormalities are common in falciparum malaria, and mild thrombocytopenia is usual. Fewer than 5% of patients with severe malaria have significant bleeding with evidence of disseminated intravascular coagulation. Hematemesis, presumably from stress ulceration or acute gastric erosions, may also occur.

Aspiration pneumonia following convulsions is an important cause of death in cerebral malaria. Chest infections and catheter-induced urinary tract infections are common among patients who are unconscious for more than 3 days. Septicemia may complicate severe malaria; in endemic areas, *Salmonella* bacteremia has been associated specifically with *P. falciparum* infections.

## Malaria in Pregnancy

In hyperendemic and holoendemic areas, falciparum malaria especially in primigravid and secundigravid women is associated with low birth weight (average reduction, ~170 g) and consequently increased neonatal mortality. In general, infected mothers in areas of stable transmission remain asymptomatic despite intense accumulation of parasitized erythrocytes in the placental microcirculation. Maternal HIV infection predisposes pregnant women to malaria and predisposes their newborns to congenital malaria infection and low birth weight.

In areas with unstable transmission of malaria, pregnant women are prone to severe infection and are particularly vulnerable to developing severe malaria with high-density parasitemias, anemia, hypoglycemia, and acute pulmonary edema. Fetal distress, premature labor, and stillbirth or low birth weight are common. Congenital malaria occurs in fewer than 5% of newborns whose mothers are infected and is related directly to the parasite density in maternal blood and in the placenta. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight (average, 100 g), but, in contrast with the situation in falciparum malaria, this effect is greater in multigravid than in primigravid women.

## Malaria in Children

Most of the estimated 1 to 3 million persons who die of falciparum malaria each year are young African children. In endemic areas there is considerable diagnostic overlap between septicemia and severe malaria. Convulsions, coma, hypoglycemia, metabolic acidosis, and severe anemia are more common among children with severe malaria than in adults, whereas deep jaundice, acute renal failure, and acute pulmonary edema are unusual in childhood. Severely anemic children may have labored deep breathing, which in the past has been attributed incorrectly to “anemic congestive cardiac failure” but is caused by metabolic acidosis, often compounded by hypovolemia. In general, children tolerate anti-malarial drugs well and respond rapidly to treatment.

## Transfusion Malaria

Malaria can be transmitted by blood transfusion, needle-stick injury, sharing of needles by infected drug addicts, or organ transplantation. The incubation period in these settings is often short because there is no pre-erythrocytic stage of development. The clinical features and management of these cases are the same as for naturally acquired infections. Radical chemotherapy with primaquine is unnecessary for blood-transmitted *P. vivax* and *P. ovale* infections.

## Hyperreactive Malarial Splenomegaly

Chronic or repeated malarial infections produce hypergammaglobulinemia; normochromic, normocytic anemia; and, in certain situations, splenomegaly. Some residents of malaria-endemic areas of tropical Africa and Asia exhibit an abnormal immunologic response to repeated infection that is characterized by massive splenomegaly, hepatomegaly, marked elevations in serum titers of IgM and malarial

antibody, hepatic sinusoidal lymphocytosis, and (in Africa) peripheral B-cell lymphocytosis. This syndrome has been associated with the production of cytotoxic IgM antibodies to suppressor (CD8+) lymphocytes, antibodies to CD4+ T cells, and an increase in the ratio of CD4+ T cells to CD8+ T cells.<sup>56</sup> These events may lead to uninhibited B-cell production of IgM and the formation of cryoglobulins (IgM aggregates and immunocomplexes). This immunologic process stimulates reticuloendothelial hyperplasia and clearance activity and eventually produces splenomegaly. Patients with hyperreactive malarial splenomegaly (HMS) feel an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. Anemia and some degree of pancytopenia are usually evident, but in many cases malarial parasites cannot be found in peripheral blood smears. Vulnerability to respiratory and skin infections is increased; many patients die of overwhelming sepsis. Persons with HMS who are living in endemic areas should receive antimalarial chemoprophylaxis; the results are usually good. In nonendemic areas, antimalarial treatment is advised. In some cases refractory to therapy, clonal lymphoproliferation may develop and then evolve to a malignant lymphoproliferative disorder.

### Quartan Malarial Nephropathy

Chronic or repeated infections with *P. malariae*, and possibly other malarial species, may cause soluble immunocomplex injury to the renal glomeruli, resulting in the nephrotic syndrome. Other unidentified factors must contribute to this process, since only a small proportion of infected patients develop renal disease. The histologic appearance is that of focal or segmental glomerulonephritis with splitting of the capillary basement membrane. Subendothelial dense deposits are seen on electron microscopy, and immunofluorescence reveals deposits of complement and immunoglobulins; in samples of renal tissue from children, *P. malariae* antigens are often visible. A coarse-granular pattern of basement membrane immunofluorescent deposits (predominantly IgG3) with selective proteinuria carries a better prognosis than a fine-granular, predominantly IgG2 pattern with nonselective proteinuria. Quartan nephropathy usually responds poorly to treatment with either antimalarial agents or glucocorticoids and cytotoxic drugs.

### Burkitt's Lymphoma and Epstein-Barr Virus Infection

It is possible that malaria-related immunosuppression promotes infection with lymphoma viruses. Burkitt's lymphoma is strongly associated with Epstein-Barr virus. The prevalence of this childhood tumor is high in malarious areas of Africa.

### Laboratory Findings

Normochromic, normocytic anemia is usual. The leukocyte count is generally normal, although it may be raised in very severe infections. The erythrocyte sedimentation rate, plasma viscosity, and levels of C-reactive protein and other acute-phase proteins are high. The platelet count is usually reduced to approximately  $10^5/\mu\text{L}$ . Severe infections may be accompanied by

prolonged prothrombin and partial thromboplastin times and by more severe thrombocytopenia. In uncomplicated malaria, plasma concentrations of electrolytes, blood urea nitrogen, and creatinine are usually normal. Findings in severe malaria may include metabolic acidosis, with low plasma concentrations of glucose, sodium, bicarbonate, calcium, phosphate, and albumin together with elevations in lactate, blood urea nitrogen, creatinine, urate, muscle and liver enzymes, and conjugated and unconjugated bilirubin. Hypergammaglobulinemia is usual in immune and semi-immune subjects, and urinalysis generally gives normal results. In adults and children with cerebral malaria, the mean opening pressure at lumbar puncture is approximately 160 mm of cerebrospinal fluid (CSF); the CSF is usually normal or has a slightly elevated total protein level [ $<1.0 \text{ g/L}$  ( $100 \text{ mg/dL}$ )] and cell count ( $<20/\mu\text{L}$ ).

## PATHOGENESIS

The pathophysiology of malaria results from destruction of erythrocytes (both infected and uninfected), the consequent liberation of parasite and erythrocyte material into the circulation, and the host reaction to these events. *P. falciparum* malaria-infected erythrocytes specifically sequester in the microcirculation of vital organs, interfering with microcirculatory flow and host tissue metabolism.

### Toxicity and the Role of Cytokines

No potent malaria toxin has been identified, but malaria parasites do induce release of cytokines in much the same way as bacterial endotoxin does.<sup>57</sup> A glycolipid material with some similarities to bacterial endotoxin is released on schizont rupture. This is derived from the glycosylphosphatidylinositol anchor that covalently links proteins including the malaria parasite surface antigens to the cell membrane lipid bilayer. Malaria antigen-related IgE complexes also activate cytokine release. These malaria parasite products, like the endotoxin of bacteria, induce activation of the cytokine cascade, but they are *considerably* less potent than bacteria. For example, an *E. coli* bacteremia of 1 bacterium/mL carries an approximate mortality of 20%, whereas in falciparum malaria only parasitemias of well over  $10^9/\text{mL}$  have such a lethal effect. Cells of the macrophage-monocyte series,  $\gamma\delta$  T cells,  $\alpha/\beta$  T cells, CD14+ cells, and possibly endothelium, are stimulated to release cytokines in a mutually amplifying chain reaction. Initially, tumor necrosis factor alpha (TNF- $\alpha$ ), which plays a pivotal role, interleukin (IL)-1, and  $\gamma$ -interferon are produced and in turn induce release of a cascade of other "pro-inflammatory" cytokines including IL-8, IL-12, IL-18. These are balanced by production of the "anti-inflammatory" cytokines IL-6 and IL-10. Cytokines are responsible for many symptoms and signs of the infection, particularly fever and malaise. Plasma inflammatory cytokine concentrations are elevated in both acute vivax and falciparum malaria.<sup>58</sup> In established vivax malaria, which tends to synchronize earlier than *P. falciparum*, a pulse release of TNF occurs at the time of schizont rupture and is followed by the characteristic symptoms and signs of the "paroxysm," i.e., shivering, cool extremities, headache, chills, a spike of fever, and sometimes rigors followed by sweating, vasodilatation, and defervescence. For a given number of parasites, *P. vivax* is a more potent inducer of

TNF release than *P. falciparum*, which may explain why it has a lower pyrogenic density.

There is a positive correlation between cytokine levels and prognosis in severe falciparum malaria and a disturbed balance between pro- and anti-inflammatory cytokines.<sup>58</sup> Acute malaria is associated with high levels of most cytokines, but the balance differs in relation to severity. IL-12 and TGF- $\beta$ 1, which may regulate the balance between pro- and anti-inflammatory cytokines, are higher in uncomplicated than in severe malaria. IL-10, a potent anti-inflammatory cytokine, increases markedly in severe malaria but, in fatal cases, does not increase sufficiently to restrain the production of TNF.<sup>58</sup> A reduced IL-10/TNF ratio has also been associated with childhood malarial anemia in areas of high transmission.

Does TNF play a causal role in cerebral dysfunction or death from severe malaria? Genetic studies from Africa indicate that children with the (308A) TNF2 allele, a polymorphism in the TNF promoter region, have a relative risk of 7 for death or neurologic sequelae from cerebral malaria.<sup>59</sup> A separate polymorphism in this region that affects gene expression was associated with a fourfold increased risk of cerebral malaria. On the other hand, the clinical studies in cerebral malaria with anti-TNF antibodies and other strategies to reduce TNF production reported to date have shown no convincing effects other than reduction in fever. Furthermore the 308 polymorphism is not associated with fatal cerebral malaria in Asian adults.<sup>60</sup> There is no direct evidence that systemic release of TNF or other cytokines causes coma in humans (although mechanisms involving release of nitric oxide within the central nervous system (CNS) and consequent inhibition of neurotransmission can be hypothesized). In adults with severe malaria, elevated plasma TNF concentrations have been associated specifically with renal dysfunction,<sup>57,58</sup> and TNF levels were actually lower in patients with pure cerebral malaria compared with those with other manifestations of severe disease. Severe malarial anemia has been associated with a different TNF promoter polymorphism (238A; odds ratio 2.5).

Cytokines are probably involved in placental dysfunction, suppression of erythropoiesis, and inhibition of gluconeogenesis, and do cause fever in malaria. Tolerance to malaria, or premunition, reflects both immune regulation of the infection and also reduced production of cytokines in response to malaria ("antitoxic immunity"). Cytokines may also be important mediators of parasite killing by activating leukocytes, and possibly other cells, to release toxic oxygen species and nitric oxide, and by generating parasitocidal lipid peroxides and causing fever. So, whereas high concentrations of cytokines may be harmful, lower levels probably promote parasite clearance and thereby benefit the host.

## Sequestration and Cytoadherence

Erythrocytes containing mature forms of *P. falciparum* adhere to microvascular endothelium ("cytoadherence") and thus disappear from the circulation. This is called sequestration, and it starts at approximately 12 hours of asexual development. The process is accelerated by fever. Sequestration does not occur to a significant extent with the other three human malaria parasites. Sequestration is thought to be central to the pathophysiology of falciparum malaria, since it interferes with microcirculatory flow.<sup>61</sup> Once infected red cells adhere, they do

not enter the circulation again, remaining stuck until they rupture at merogony (schizogony). As a consequence, whereas in the other malarias of humans, mature parasites are commonly seen on blood smears, these forms are rare in falciparum malaria and often indicate serious infection. It was thought that ring stage infected erythrocytes do not cytoadhere at all, but recent pathologic and laboratory studies show that they do, although much less so than more mature stages. Sequestration occurs predominantly in the venules of vital organs. It is greatest in the brain, particularly in the white matter; prominent in the heart, eyes, liver, kidneys, intestines, and adipose tissue; and least frequent in the skin. Even within the brain, the distribution of sequestered erythrocytes varies markedly from vessel to vessel,<sup>61</sup> presumably reflecting differences in the local expression of endothelial receptors. Cytoadherence and the related phenomenon of rosetting lead to microcirculatory obstruction in falciparum malaria. The consequences of microcirculatory obstruction are activation of the vascular endothelium and reduced oxygen and substrate supply, which leads to anaerobic glycolysis, lactic acidosis, and cellular dysfunction.

Cytoadherence is mediated by several different processes. The most important parasite ligands are a family of strain-specific, high-molecular-weight, parasite-derived proteins termed *P. falciparum* erythrocyte membrane protein 1, or PfEMP1. These proteins (molecular mass 240 to 260 kD) are encoded by *var* genes, a family of over 50 genes distributed throughout the parasite's genome.<sup>19–21</sup> PfEMP1 is transcribed, synthesized, and stored within the parasite and, beginning at around 12 hours of development, is then exported to the surface of the infecting erythrocyte. These accretions cause humps or knobs on the surface of the red cell, and these are the points of attachment to vascular endothelium. PfEMP1 expression is greatest at the middle of the asexual cycle. PfEMP1 also appears to be a major antigenic determinant for the blood-stage parasite. As in other protozoal parasites, the immunodominant surface antigen undergoes antigenic variation to "change its coat" and avoid immune mediated attack. *P. falciparum* "switches" to a new variant of PfEMP1 at a rate of at least 2% per cycle.<sup>62</sup> In the chronic phase of untreated infection, this results in small waves of parasitemia approximately every 3 weeks. The central role of parasite-derived proteins in cytoadherence is not accepted by all. It has been suggested that cytoadherence is mediated by altered red cell membrane components such as a modified form of the red cell cytoskeleton protein band 3 (the major erythrocyte anion transporter, also called *Pf*alhesin). In culture, most parasites lose the ability to cytoadhere after several cycles of replication. In vivo, cytoadherence may be modulated by the spleen. In those patients who have had a splenectomy and who develop falciparum malaria, all stages of the parasite can be seen in peripheral blood smears.

## Vascular Endothelial Ligands

Several different sticky proteins present on the surface of vascular endothelium have been shown to bind parasitized red cells. The interaction between these proteins and the variant surface adhesin of the parasitized red cell is complex. Probably the most important protein is the leukocyte differentiation antigen CD36<sup>63</sup>; nearly all freshly obtained parasites bind to CD36. Binding is increased at low pH (<7.0) and

in the presence of high calcium concentrations. CD36 is constitutionally expressed on vascular endothelium and monocytes/macrophages although usually it is not present on the surface of cerebral vessels. CD36 is expressed on platelets, and platelets may form a bridge between infected erythrocytes and vascular endothelium. The intercellular adhesion molecule (ICAM1), which is also the receptor for rhinovirus attachment, appears to be the major cytoadherence receptor in the brain.<sup>64</sup> Expression of ICAM1, but not CD36, is up-regulated by cytokines (notably TNF). At physiologic shear rates (i.e., those likely to be encountered in the human microcirculation) the binding forces ( $\approx 10^{-10}$ N) are similar for CD36 and ICAM1. Binding to the two ligands is synergistic.<sup>65</sup> Once stuck, the parasitized erythrocytes remain attached until schizont rupture, and then the residual ghost's membranes (sometimes with attached malaria pigment) often remain tethered within the vessel. Thrombospondin (a natural ligand to CD36) also binds to some parasitized red cells (probably to modified band 3), and recently the ubiquitous proteins VCAM, PECAM, E-selectin, and  $\alpha/\beta$  integrin have also been shown to bind in some circumstances.<sup>65</sup> P-selectin has been shown to mediate rolling. The relative importance of these molecules and their interactions is still not clear. Chondroitin sulfate A (CSA) appears to be a major receptor for cytoadherence in the placenta.<sup>66</sup> Hyaluronic acid also has been proposed as a candidate for placental adhesion. Antibodies that inhibit parasitized red cell cytoadherence to CSA are generally present in multigravidae in endemic areas but not in primigravidae.<sup>67</sup> This may explain why the adverse effects of pregnancy on birth weight are greater in primigravidae. Other as yet unidentified vascular receptors are also present, since sequestration also occurs in vessels expressing none of the potential ligands identified so far. Thus, ICAM1 appears to be the major vascular ligand in the brain involved in cerebral sequestration, CSA is the major ligand in the placenta, and CD36 is probably the major ligand in the other organs and also in platelet-mediated cytoadherence. Severity is related to the number of parasites in the body and distribution of cytoadherence within the vital organs. The relative importance of parasite phenotype and the various potential vascular ligands in the pathophysiology of severe falciparum malaria and the precise role of the spleen remain to be determined.

### Rosetting and Aggregation

Erythrocytes containing mature parasites also adhere to uninfected erythrocytes.<sup>68</sup> This process leads to the formation of "rosettes" when suspensions of parasitized erythrocytes are viewed under the microscope. Rosetting shares some characteristics of cytoadherence. It starts at around 16 hours of the asexual life cycle development (slightly after cytoadherence begins) and is trypsin-sensitive. However, parasite species that do not sequester do form rosettes, and unlike cytoadherence, rosetting is inhibited by certain heparin subfractions and calcium chelators. Furthermore, whereas all fresh isolates of *P. falciparum* cytoadhere, not all rosette. Rosetting is mediated by attachment of specific domains of PfEMP1 to the complement receptor CR1, heparan sulfate, blood group A antigen, and probably other red cell surface molecules. Attachment is facilitated by serum components. Rosetting has been associated with severe malaria in some studies but not in others.<sup>69</sup> It has been suggested that rosetting might encourage

cytoadherence by reducing flow (shear rate), which would enhance anaerobic glycolysis, reduce pH, and facilitate adherence of infected erythrocytes to venular endothelium. Rosetting tends to start in venules, and this certainly could reduce flow. The adhesive forces involved in rosetting could also impede forward flow of uninfected erythrocytes as they squeeze past sticky cytoadherent parasitized red cells in capillaries and venules. The mechanical obstruction, or "static hindrance," would be compounded by the lack of deformability of the adherent and circulating parasitized red cells. Recently, a new adherence property of parasitized red cells has been characterized and associated with disease severity in African children and Thai adults.<sup>70</sup> This is the platelet mediated aggregation of parasitized erythrocytes and is mediated via platelet CD36. These cells clump together in ex vivo cultures. Aggregation could also contribute to vascular occlusion.

### Erythrocyte Deformability

As the parasite matures inside the erythrocyte, the normally flexible biconcave disc becomes progressively more spherical and rigid. The reduction in deformability results from reduced membrane fluidity, increasing sphericity, and the enlarging and relatively rigid intraerythrocytic parasite. Loss of uninfected red cell deformability has been recognized recently as a major contributor to disease severity and outcome. Increased erythrocyte rigidity measured at the low shear stresses encountered in capillaries and venules is correlated closely with outcome in severe malaria.<sup>71</sup> When assessed at the shear rates encountered on the arterial side, and importantly in the spleen, reduced red cell deformability correlates with anemia. This is a malaria-specific phenomenon, since it is not found in severe sepsis.

### Immunologic Processes

It is unlikely that severe malaria, in particular cerebral malaria, results from specific immune-mediated damage. In relation to the degree of parasitized red cell sequestration, relatively few leukocytes are found in or around the cerebral vessels in fatal cases (although there are more in African children than in adults studied in Southeast Asia). Thus, there is little pathologic evidence in humans for widespread cerebral vasculitis. Indeed, fatal falciparum malaria is remarkable for the lack of extravascular pathology. Despite the enormous intravascular antigenic load in malaria, with the formation and deposition of immunocomplexes and variable complement depletion, there is little evidence of a specific immunopathologic process in severe malaria.

Acute malaria infections are associated with malaria antigen-specific unresponsiveness. This selective paresis is one of the factors contributing to the slow development of an effective and specific immune response in malaria. Acute malaria is characterized by nonspecific polyclonal B-cell activation. There is a reduction in circulating T cells with an increase in the  $\gamma\delta$  T-cell subset, but other T-cell proportions usually are normal. Although residents of hyperendemic or holoendemic malarious areas have hypergammaglobulinemia, most of this antibody is not directed against malaria antigens. In nonimmune individuals, the acute antibody response to infection often comprises mostly IgM or IgG<sub>2</sub> isotypes, which are unable to arm cytotoxic cells and thus kill asexual malaria parasites.

These observations have led to the suggestion that malaria induces an immunologic “smoke screen” with broad-spectrum and nonspecific activation that interferes with the orderly development of a specific cellular immune response. In severe malaria there is evidence of a broader immune suppression, with defects in monocyte and neutrophil chemotaxis, reduced monocytic phagocytic function, and a tendency to bacterial superinfection.

In the nephrotic syndrome associated with chronic *P. malariae* infections, malaria antigen and immunocomplexes can be eluted from the kidney, indicating a role for quartan malaria in this condition. Why some children are affected while the majority are not is unresolved.

### Cerebral Malaria

In the past it was suggested that cerebral malaria resulted from an increase in cerebral capillary permeability, which led to brain swelling, coma, and death. There is evidence of a mild generalized increase in systemic vascular permeability in severe malaria. It is now clear from imaging studies that the majority of adults and children with cerebral malaria show no evidence of cerebral edema. However, the role of raised intracranial pressure in cerebral malaria remains unclear. Whereas 80% of adults have opening pressures at lumbar puncture that are in the normal range (<200 mm CSF), 80% of children have elevated opening pressures (>100 mm CSF; the normal range is lower in children), and intracranial pressure may rise transiently to very high levels. Some patients with cerebral malaria die of acute respiratory arrest with neurologic signs that are compatible with brainstem compression. However, these signs are also common and may persist for many hours in survivors.<sup>72</sup> The elevation in opening pressure usually is not great (in general it is much lower than in bacterial or fungal meningitis), and there is no difference between these lumbar puncture opening pressures in surviving children and fatal cases. Studies of computerized tomography (CT) or magnetic resonance imaging (MRI) generally show slight brain swelling in cerebral malaria (compatible with an increased intracerebral blood volume).<sup>73</sup> Immunohistochemical studies on autopsy brain tissues indicates focal disruption of endothelial junctions and endothelial activation in areas of intense sequestration, but clinical investigation have also failed to detect major alterations in blood-brain barrier permeability. Thus, raised intracranial pressure probably arises from an increase in cerebral blood volume, independent of permeability.<sup>74</sup> This results from the circulating blood required to maintain cerebral perfusion and a considerable sequestered static biomass of intracerebral parasites. Children may be particularly vulnerable, since after the skull sutures have fused, there is less space for cranial expansion than in adults. The possibility that a sudden rise in intracranial pressure accounts for some deaths cannot be excluded.<sup>74</sup>

The cause of coma in cerebral malaria is not known. Undoubtedly there is an increase in cerebral anaerobic glycolysis with cerebral blood flows that are inappropriately low for the arterial oxygen content, increased cerebral metabolic rates for lactate, and increased CSF concentrations of lactate, but these changes do not provide sufficient explanation for coma. Presumably the metabolic milieu created adjacent to the sequestered and highly metabolically active parasites

and their attachment to the activated cerebral vascular endothelium interferes with endothelial and blood-brain barrier function. But how this interferes with neurotransmission is not known. Recent studies point to a disruption of axonal transport as the most likely explanation for rapidly reversible neurologic deficit. Cytokines increase production of nitric oxide, a potent inhibitor of neurotransmission, by leukocytes, smooth muscle cells, microglia, and vascular endothelium through induction of the enzyme nitric oxide synthase. Inducible nitric oxide synthase expression is increased in the brain in fatal cerebral malaria.

### Renal Failure

There is renal cortical vasoconstriction and consequent hypoperfusion in severe falciparum malaria. In patients with acute renal failure (ARF), renal vascular resistance is increased. The renal injury in severe malaria results in acute tubular necrosis. The oxygen consumption of the kidneys is reduced in ARF, and it is not improved by dopamine-induced arteriolar vasodilatation and consequent increase in renal blood flow suggesting a fixed injury.<sup>75</sup> Acute tubular necrosis presumably results from renal microvascular obstruction and cellular injury consequent upon sequestration in the kidney and the filtration of free hemoglobin, myoglobin, and other cellular material. Significant glomerulonephritis is rare. Massive hemolysis compounds the insult in blackwater fever complicating malaria, and hemoglobinuria may itself lead to renal impairment. Mild renal impairment occurs in young children with severe malaria, but established ARF is almost confined to older children and adults.

### Pulmonary Edema

Despite intense sequestration in the myocardial vessels, the heart's pump function is remarkably well preserved in severe malaria. Pulmonary edema in malaria results from a sudden increase in pulmonary capillary permeability that is not reflected in other vascular beds.<sup>76</sup> The pulmonary capillary wedge pressure is usually normal, and the threshold for the development of pulmonary edema is relatively low. Whereas ARF, severe metabolic acidosis, and coma are seen only in falciparum malaria, acute pulmonary edema may also occur in vivax malaria. The cause of this increase in pulmonary capillary permeability is not known.

### Fluid Space and Electrolyte Changes

Following rehydration, the plasma volume is increased in moderate and severe malaria. Total body water and extracellular volume are usually normal or slightly reduced—even in children who are acidotic. Plasma renin activity, aldosterone, and antidiuretic hormone concentrations are elevated, reflecting an appropriate activation of homeostatic mechanisms to maintain adequate circulating volume in the presence of general vasodilatation and a falling hematocrit. Mild hyponatremia and hypochloremia are common in severe malaria, but serum potassium concentrations usually are normal. Occasionally hyponatremia is severe. Studies in Kenyan children indicate inappropriate antidiuretic hormone (arginine vasopressin) secretion in two thirds of cases.<sup>77</sup>

## Anemia

The pathogenesis of anemia is multifactorial. There is obligatory destruction of red cells containing parasites at merozoites, accelerated destruction of nonparasitized red cells that parallels disease severity, and bone marrow dyserythropoiesis. In severe malaria, anemia develops rapidly; the rapid hemolysis of unparasitized red cells is the major contributor to the decline in hematocrit.<sup>78</sup> Bone marrow dyserythropoiesis persists for days or weeks following acute malaria, and reticulocyte counts are usually low in the acute phase of the disease. The cause of the dyserythropoiesis is thought to be related to intramedullary cytokine production. Serum erythropoietin levels are usually elevated, although in some series it has been suggested that the degree of elevation was insufficient for the degree of anemia.

In falciparum malaria, the entire red cell population (i.e., both infected and uninfected red cells) becomes more rigid. This loss of deformability correlates with disease severity and outcome and, when measured at the high shear rates encountered in the spleen, with the degree of resulting anemia. The mechanism responsible has not been identified although there is evidence in acute malaria for increased oxidative damage, which might compromise red cell membrane function and deformability.

The role of antibody (i.e., Coombs'-positive hemolysis) in anemia is unresolved. The majority of studies do not show increased red cell immunoglobulin binding in malaria, but in the presence of a lowered recognition threshold for splenic clearance, this might be difficult to detect. The splenic threshold for the clearance of abnormal erythrocytes, whether because of antibody coating or reduced deformability, is lowered. Thus, the spleen removes large numbers of relatively rigid cells, resulting in shortened erythrocyte survival, particularly in severe malaria. This is unaffected by corticosteroids.

In the context of acute uncomplicated malaria, the anemia is worse in younger children and those with protracted infections. Loss of unparasitized erythrocytes accounts for approximately 90% of the acute anemia resulting from a single infection. Iron deficiency and malaria often coincide in the same patient, and in some areas routine iron supplementation following malaria promotes recovery from anemia.

## Coagulopathy and Thrombocytopenia

There is accelerated coagulation cascade activity with accelerated fibrinogen turnover, consumption of antithrombin III, reduced factor XIII, and increased concentrations of fibrin degradation products in acute malaria. In severe infections, the prothrombin and partial thromboplastin times may be prolonged, and in occasional patients (<5%) bleeding may be significant. The coagulation cascade is activated via the intrinsic pathway. Intravascular thrombus formation is observed rarely at autopsy in fatal cases and fibrin deposition is sparse and platelets are strikingly unusual.

Thrombocytopenia is common to all four human malarias and is caused by increased splenic clearance. Platelet turnover is increased.<sup>79</sup> The role of platelet-bound antibody in malarial thrombocytopenia is controversial. There is evidence of platelet activation in some studies but not others. Erythrocytes containing mature parasites may activate the coagulation cascade

directly, and cytokine release is also procoagulant. It was suggested in the past that disseminated intravascular coagulation (DIC) is important in the pathogenesis of severe malaria, but detailed prospective clinical and pathogenesis studies have refuted this. Coagulation cascade activity is directly proportional to disease severity, but hypofibrinogenemia resulting from DIC is significant in less than 5% of patients with severe malaria, and lethal hemorrhage (usually gastrointestinal) is quite unusual.

## Blackwater Fever

This is a poorly understood condition in which there is massive intravascular hemolysis and the passage of Coca-Cola-colored urine. Blackwater (urine) occurs in three circumstances: (1) when patients with G6PD deficiency take oxidant drugs (e.g., primaquine or sulphonamides) irrespective of whether they have malaria, (2) occasionally when patients with G6PD deficiency have malaria and receive quinine treatment, and (3) in some patients with severe, quinine-treated falciparum malaria who have normal erythrocyte G6PD levels. How quinine causes blackwater in these last two situations is not known, since it is not an oxidant drug. G6PD-deficient red cells are particularly susceptible to oxidant stress because they are unable to synthesize adequate quantities of NADPH through the pentose shunt. This leads to low intraerythrocytic levels of reduced glutathione and both alterations in the erythrocyte membrane and increased susceptibility to organic peroxides. Blackwater fever may be associated with acute renal failure, although in most cases renal function remains normal.

## The Spleen

There is considerable splenic enlargement in malaria and an increased capacity to clear red cells from the circulation both by Fc receptor-mediated (immune) mechanisms and by recognition of reduced deformability (filtration). The increased filtration of the spleen and the reduced deformability of the entire red cell population result in the rapid development of anemia in severe malaria. The spleen may also modulate cytoadherence. It plays a central role in limiting the acute expansion of the malaria infection by removing parasitized erythrocytes, and this has led to the suggestion that a failure to augment splenic clearance sufficiently rapidly may be a factor in the development of severe malaria. The spleen is capable of removing damaged intraerythrocytic parasites and returning the once infected red cells to the circulation (a process known as "pitting"),<sup>80</sup> where they have shortened survival. This is an important contributor to parasite clearance following antimalarial drug treatment (particularly treatment with artemisinin derivatives).

## Gastrointestinal Dysfunction

Abdominal pain may be prominent in acute malaria. Minor stress ulceration of the stomach and duodenum is common in severe malaria. The pattern of malabsorption of sugars, fats, and amino acids suggests reduced splanchnic perfusion. This results from both gut sequestration and visceral vasoconstriction. Gut permeability is increased, and this

may be associated with reduced local defenses against bacterial toxins or even whole bacteria in severe disease. Antimalarial drug absorption is remarkably unaffected in uncomplicated malaria, except for those drugs which have fat (i.e., food) dependent absorption (halofantrine, atovaquone, lumefantrine).

## Liver Dysfunction

Jaundice is common in adults with severe malaria, and there is other evidence of hepatic dysfunction, with reduced clotting factor synthesis, reduced metabolic clearance of the antimalarial drugs, and a failure of gluconeogenesis, which contributes to lactic acidosis and hypoglycemia. Nevertheless, true liver failure (as in fulminant viral hepatitis) is unusual. There is sequestration in the hepatic microvasculature, and although many patients with acute falciparum malaria have elevated liver blood flow values, in very severe infections liver blood flow is reduced. Liver blood flow values less than 15 mL/kg/min are associated with elevated venous lactate concentrations, suggesting a flow limitation to lactate clearance and thus a contribution of liver dysfunction to lactic acidosis. Recent direct measurements of hepatic venous lactate concentrations in severe malaria confirm that the hepatosplanchnic extraction ratio is inversely correlated with mixed venous plasma lactate (i.e., hyperlactatemia is associated with reduced liver clearance of lactate). There is no relationship between liver blood flow and impairment of antimalarial drug clearance. Jaundice in malaria appears to have hemolytic and cholestatic components. Cholestatic jaundice may persist well into the recovery period.

## Acidosis

Acidosis is a major cause of death in severe falciparum malaria. Recent studies indicate that the main acid (i.e., the main contributor to the anion gap) is unidentified. There is commonly a lactic acidosis, although ketoacidosis (and sometimes salicylate intoxication) may predominate in children, and the acidosis of renal failure is common in adults.<sup>81,82</sup> In severe malaria, the arterial, capillary, venous and CSF concentrations of lactate rise in direct proportion to disease severity. In bacterial sepsis there is hyperlactatemia, but unless there is profound shock, the lactate-pyruvate ratio is usually less than 15. This indicates that hypermetabolism is the source of lactate accumulation in sepsis. In severe malaria the pathogenesis is different; lactate-pyruvate ratios often exceed 30, reflecting tissue hypoxia and anaerobic glycolysis.

Lactic acidosis results from several discrete processes: the tissue anaerobic glycolysis consequent upon microvascular obstruction; a failure of hepatic and renal lactate clearance; and the production of lactate by the parasite. Lactate turnover in both adults and children with severe malaria is increased approximately threefold compared with values obtained in healthy adults.<sup>83</sup> Studies in children using stable isotope techniques indicate that increased lactate production (resulting from anaerobic glycolysis) rather than reduced clearance is the main cause of lactate accumulation although in adults reduced clearance is certainly a contributor. Hyperlactatemia is associated with hypoglycemia and is accompanied by hyperalaninemia and elevated glycerol concentrations, reflecting the impairment of gluconeogenesis

through the Cori cycle. Lactate, glutamine, and alanine are the major gluconeogenic precursors. Triglyceride and free fatty acid levels are also elevated in acute malaria, and plasma concentrations of ketone bodies are raised in patients who have been unable to eat. Ketoacidosis may be prominent in children.

In severe malaria there is dysfunction of all organ systems, particularly those with obligatory high metabolic rates. The endocrine glands are no exception. Pituitary-thyroid axis abnormalities result in the “sick euthyroid” syndrome and also parathyroid dysfunction. Mild hypocalcemia is common, and hypophosphatemia may be profound in the very seriously ill. By contrast, the pituitary-adrenal axis appears normal in acute malaria.

## Hypoglycemia

Hypoglycemia is associated with hyperlactatemia and shares the same pathophysiological etiology: an increased peripheral requirement for glucose consequent upon anaerobic glycolysis (the Pasteur effect), the increased metabolic demands of the febrile illness<sup>83</sup> and the obligatory demands of the parasites that use glucose as their major fuel (all of which increase demand), and a failure of hepatic gluconeogenesis and glycogenolysis (reduced supply).<sup>84</sup> Hepatic glycogen is exhausted rapidly: stores in fasting adults last approximately 2 days, but children have enough for only 12 hours. Healthy children have approximately three times higher rates of glucose turnover compared with adults, but in severe malaria turnover is increased by more than 50% (to values five times higher than those in adults with severe malaria). The net result of impaired gluconeogenesis, limited glycogen stores, and greatly increased demand results in a hypoglycemia in 20% to 30% of children with severe malaria.<sup>85,86</sup> In patients treated with quinine, this is compounded by quinine-stimulated pancreatic  $\beta$ -cell insulin secretion.<sup>84</sup> Hyperinsulinemia is balanced by reduced tissue sensitivity to insulin, which returns to normal as the patient improves. This probably explains why quinine-induced (hyperinsulinaemic) hypoglycemia tends to occur after the first 24 hours of treatment, whereas malaria-related hypoglycemia (with appropriate suppression of insulin secretion) is often present when the patient with severe malaria is first admitted. Hypoglycemia contributes to nervous system dysfunction, and in cerebral malaria is associated with residual neurologic deficit in survivors.

## Placental Dysfunction

Pregnancy increases susceptibility to malaria. This is probably caused by a suppression of systemic and placental cell-mediated immune responses. There is intense sequestration of *P. falciparum*-infected erythrocytes in the placenta, local activation of pro-inflammatory cytokine production, and maternal anemia. This leads to placental insufficiency and fetal growth retardation. Illness close to term results in prematurity. In areas of intense transmission, a malaria attributable reduction in birth weight ( $\approx 170$  g) is confined to primigravidae.<sup>87</sup> There is no convincing evidence that malaria causes abortion or stillbirth in this context. With lower levels of transmission (i.e., less immunity) the risk extends to other pregnancies, and there is a propensity to develop severe malaria with a high incidence of fetal death. The recent discovery that *P. vivax*, a

parasite not thought to cytoadhere, also reduces birth weight (by about two thirds the amount caused by *P. falciparum*), puts into question the primary role of sequestration in the pathogenesis of placental insufficiency.<sup>88</sup>

### Bacterial Infection

Patients with severe malaria are vulnerable to bacterial infections, particularly of the lungs and urinary tract (following catheterization). Postpartum sepsis is common. Spontaneous bacterial septicemia may also occur. It is relatively unusual in adults (probably less than 1% of cases) but is much more common in young children. In malaria-endemic areas, where parasitemia is common in children, it may be difficult to distinguish bacterial infections with *coincident* parasitemia from infections complicating malaria. *Salmonella* septicemias are an important complication of otherwise uncomplicated falciparum malaria in African children.

### DIAGNOSIS

Prompt and accurate diagnosis of malaria is the key to effective disease management. Since malaria cannot be diagnosed clinically, blood must be examined either by microscopy, after staining thick and thin films (Giemsa at pH 7.2 is preferred; Wright's, Field's, or Leishman's can also be used), or by rapid antigen detection tests (RDTs). Staining of parasites with the fluorescent dye acridine orange is an alternative that allows more rapid diagnosis of malaria (but not speciation of the infection) in patients with low parasitemias.<sup>89</sup> Polymerase chain reaction (PCR) is more sensitive than other methods of diagnosis but is still a research tool.<sup>90</sup>

In many endemic areas, a high percentage of individuals (often 95% of children and 50% of adults) always have low densities of *P. falciparum* in their blood during transmission seasons. Thus, the presence of parasites does not ensure that clinical symptoms and signs such as elevated temperature are due to malaria. Furthermore, in high transmission areas, parasitemias of up to 10,000 parasites per microliter may be tolerated without symptoms or signs in partially immune individuals. In these cases, an absolute density of parasites in the blood (often 5000 to 20,000 parasites/ $\mu$ L blood) is used to make the clinical diagnosis of malaria, and patients with lower levels of parasitemia must be investigated for other causes of their symptoms and signs. Nonetheless, few clinicians would withhold antimalaria treatment from a patient with clinical symptoms and signs and any level of parasitemia.

### Blood Films

The gold standard for diagnosis of malaria is the blood film. Thick films are optimal for diagnosis, particularly at low parasitemias, because 20 to 40 times more blood is examined. Determination of the species of parasite can often be done by an expert on a thick film but is best done on a thin film (Plate 90-1). In a patient suspected of having malaria with a negative blood film, the blood film should be examined every 12 hours for 36 to 48 hours before considering it to be negative. See Table 90-1 and Figure 90-4 for instructions on preparing blood films, comparative morphology of *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* in blood films, and examples of blood films in *P. falciparum* and *P. vivax*.

### Estimation of Parasite Density

Since one criterion for diagnosing severe malaria is the density of parasitemia (see Box 90-2), it is important, particularly in *P. falciparum* infections, to determine the density of parasitemia. The density of parasitemia is expressed as percentage of erythrocytes parasitized, or as the numbers of parasitized erythrocytes per microliter of blood. The percent parasitemia is estimated by determining the number of parasitized erythrocytes per 1000 red cells in a thin blood film. At low densities of parasitemia percent parasitemia is extremely difficult to determine, and the number of parasites/ $\mu$ L blood is estimated. The number of parasites/ $\mu$ L blood is derived from the number of parasitized erythrocytes per 200 white blood cells (WBCs), generally in a thick blood film. If the WBC count is known, then one can calculate the parasite density per microliter. For example, if there are 100 parasites per 200 WBCs and the WBC count is 6000/ $\mu$ L, the parasite density is  $(100 \text{ parasites}/200 \text{ WBCs}) \times 6000 \text{ WBCs}/\mu\text{L} = 3000 \text{ parasites}/\mu\text{L}$  blood. If the WBC count is not known, it is generally assumed to be 8000 WBCs/ $\mu$ L. The number of parasites/ $\mu$ L blood can also be estimated by knowing the percent parasitemia and the number of erythrocytes/ $\mu$ L blood. If there are  $5 \times 10^6$  erythrocytes/ $\mu$ L blood, then a 1% parasitemia corresponds to 50,000 parasitized erythrocytes/ $\mu$ L blood. An expert microscopist who examines 200 fields of a thick blood film at 1000 $\times$  magnification can detect approximately 5 parasitized erythrocytes/ $\mu$ L blood, which for an individual with  $5 \times 10^6$  erythrocytes/ $\mu$ L blood is a percent parasitemia of 0.0001%.

In the benign malarias (where sequestration is considered not to occur), the number of parasites in the body may be estimated simply by multiplying the parasite density by the estimated blood volume. In *P. falciparum* the microscopist can see only part of the first half of the asexual life cycle. In the second half of the asexual cycle the parasitized cells are sequestered. As a consequence there may be large discrepancies between the number of parasites in the peripheral (circulating) blood and the number of parasites in the body (the parasite burden). This is the reason that in a febrile patient suspected of having malaria, negative blood smears are repeated every 12 hours for 36 to 48 hours. If all of the parasites are synchronous (at the same stage of development) and sequestered, a patient with a negative blood smear read by an inexperienced microscopist, or a low parasitemia read by an experienced microscopist, could have a high parasitemia 12 to 24 hours later.

### Rapid Diagnostic Tests

Rapid, simple, sensitive, and specific antibody-based diagnostic stick or card tests (RDTs) detect *P. falciparum*-specific, histidine-rich protein (HRP) 2<sup>91,92</sup> or lactate dehydrogenase<sup>93</sup> antigens. Some of these tests incorporate a second antibody, which allows falciparum malaria to be distinguished from the less dangerous malarias. *P. falciparum* HRP2-based tests may remain positive for several weeks after acute infection. This is a disadvantage in high transmission areas where infections are highly prevalent but is of value in the diagnosis of severe malaria in patients who have taken antimalarial drugs and cleared peripheral parasitemia. Although an expert microscopist can detect as few as 5 parasites/ $\mu$ L blood, in general

B, From Chotivanich K, Silamut K, Udomsangpetch R, et al: Ex-vivo short-term culture and developmental assessment of *Plasmodium vivax*. Trans R Soc Trop Med Hyg 95:677–680, 2001.)

microscopy and RDTs have similar levels of detection at approximately 50 parasites per microliter. This also corresponds to the level at which fever develops, although many patients feel unwell for 1 or 2 days before this. A parasitemia of 50/μL corresponds to a total body parasite burden in an adult of >100 million parasites and a percent parasitemia of 0.001%.

### Blood Film Findings Useful in Identifying Patients with Poor Prognoses

#### Parasite Density

The relationship between parasitemia and prognosis is complex. Patients with >3% parasitemia (approximately  $1 \times 10^5$  parasites per microliter in a patient with anemia) are at increased risk of dying,<sup>55,94</sup> but individuals with a history of repeated infections (semi-immunes) may tolerate parasitemia levels many times higher with only minor symptoms, and some patients, especially nonimmunes, may die with much lower counts. The clue to the discrepancy lies both in the immune status of the host and in the stage of development of parasites on the peripheral blood smear.

#### Mature Parasites

A predominance of more mature parasites indicates that a greater proportion are sequestered and carries a worse prognosis for any parasitemia than does a predominance of younger forms.<sup>95</sup> In severe malaria, a poor prognosis is indicated by a predominance of more mature *P. falciparum* parasites (i.e., >20% of parasites with visible pigment) in the peripheral blood film (see Box 90-2).

#### Malaria Pigment in Polymorphonuclear Leukocytes

Another simple estimation is the number of polymorphonuclear leukocytes that contain malaria pigment.<sup>96</sup> This reflects the amount of recent schizont rupture. Patients with >5% neutrophils containing malaria pigment have an increased risk of dying (see Box 90-2).<sup>96</sup> Phagocytosed malarial pigment seen inside peripheral blood monocytes also provides a clue to recent infection if malarial parasites are not detectable. After the clearance of the parasites, malarial pigment often is evident for several days in peripheral blood phagocytes, bone marrow aspirates, or smears of fluid expressed after intradermal puncture.

### Presence of Gametocytes (Sexual Erythrocytic Stage Parasites) in Blood Films

In *P. falciparum* infection, gametocytemia peaks 1 week after the peak in asexual parasites. Gametocytes are not involved in the pathogenesis of malaria. The mature gametocytes are not affected by most antimalarial drugs, so their persistence does not constitute evidence of drug resistance.

#### Antiparasite Antibodies

In endemic areas presence of antiparasite blood-stage antibodies is used as an epidemiologic tool but in general cannot be used to determine whether an individual is infected, because virtually all individuals have such antibodies. In the

past, the presence of anti-asexual erythrocytic stage parasite antibodies was used to determine whether an individual with persistent clinical manifestations consistent with malaria, but negative blood films, might in fact have malaria. In general, the same laboratories that can assess anti-blood-stage antibodies can perform PCR, and PCR has replaced antibodies in the diagnosis of cryptic infections because it detects parasite material, not the host's immune response to the parasites.

## TREATMENT

### Antimalarial Drugs

The objective of treating severe malaria is to save life, and of treating uncomplicated malaria is to prevent the development of severe complications and cure the infection. In general the antimalarial drugs are more toxic than antibacterials, i.e., the therapeutic ratio is narrower, but serious adverse effects are rare. The available antimalarials fall into four broad groups:

1. *Quinoline-related or quinoline-like compounds.* The quinoline-related or quinoline-like compounds (quinine, quinidine, chloroquine, amodiaquine, mefloquine, halofantrine, lumefantrine, piperazine, pyronaridine) chemically interfere with intraparasitic heme detoxification, preventing the dimerization process that results in the formation of hemozoin (malaria pigment). Primaquine and tafenoquine are structurally related 8-aminoquinolines that kill liver and sexual stages of *P. falciparum* and all stages of *P. vivax*, *P. malariae*, and *P. ovale*. These are also the only drugs that kill the persistent liver stages of *P. vivax* and *P. ovale*, but their mechanism of action is unknown.
2. *Antifols.* The antifols (pyrimethamine, cycloguanil, chlorcycloguanil, trimethoprim) competitively inhibit plasmodial dihydrofolate reductase. They are synergistic with sulfonamides and sulfones. Cycloguanil and chlorcycloguanil are the active metabolites of proguanil and chlorproguanil, respectively.
3. *Artemisinin compounds.* The artemisinin compounds (artemisinin, dihydroartemisinin, artemether, artesunate) are endoperoxides naturally extracted from the naturally occurring Artemisinin plant. They have the broadest time window of action on the asexual malarial parasites, from medium-sized rings to early schizonts, and produce the most rapid therapeutic responses. They inhibit plasmodial ATPase 6 (a calcium ATPase).
4. *Atovaquone.* Atovaquone is a potent inhibitor of cytochrome-mediated electron transport. It is synergistic with proguanil (in this case, the parent compound, not the antifol metabolite cycloguanil).

Several antibacterial drugs also have antiplasmodial activity although in general their action is slow and they are used only in combination with the antimalarial drugs. Those used are the sulfonamides and sulphones, tetracyclines, lincosamides, macrolides, and chloramphenicol. Significant resistance has been reported to the sulfonamides but not to the other classes of antibiotics. Drugs that are active against sensitive *P. falciparum* are also active against the other three malaria species. The most effective antimalarial drugs are combinations of an artemisinin derivative with a slowly eliminated antimalarial drug (artemisinin combination treatments).<sup>97,98</sup>

## Pharmacokinetics

The antimalarial drugs vary considerably in their pharmacokinetic and pharmacodynamic properties (Table 90-3). Oral absorption ranges from good (quinine, chloroquine, amodiaquine, sulfadoxine-pyrimethamine, artemisinin derivatives, primaquine) to variable (mefloquine, lumefantrine, halofantrine, atovaquone). These are lipophilic hydrophobic compounds; oral absorption is increased by coadministration with fatty food or drinks. Acute malaria may cause reduced oral antimalarial absorption. Elimination rates also vary considerably from the artemisinin derivatives, which have terminal elimination half-lives ( $t_{1/2}$ ) of less than an hour; quinine, proguanil, and chlorproguanil ( $t_{1/2} < 1$  day); pyrimethamine, lumefantrine, and atovaquone ( $t_{1/2} < 1$  week), through to mefloquine, chloroquine, and piperazine, which have  $t_{1/2}$  values of weeks. Although acute malaria may impair metabolic clearance, with the exception of quinine and quinidine in severe malaria, this does not significantly affect dosing or treatment responses.

Some antimalarial drugs have active metabolites that contribute most of the antimalarial activity. In vivo artesunate is almost completely hydrolyzed to dihydroartemisinin (DHA), which is the most potent artemisinin derivative. After oral administration, artemether and artemotil are also largely converted to DHA. Amodiaquine is almost completely converted to desethylamodiaquine, and most of the antimalarial activity of proguanil and chlorproguanil derives from their antifolate triazine metabolites cycloguanil and chlorcycloguanil, respectively.

Drugs that are eliminated rapidly (artemisinins, quinine) must be given for at least 7 days to ensure high cure rates, unless they are accompanied by a more slowly eliminated partner. This why in most artemisinin combinations (ACTs), the artemisinin derivatives are partnered with slowly eliminated compounds, and the treatment course can be shortened

to a total of 3 days (Fig. 90-5).<sup>98</sup> Shorter ACT treatment courses (i.e., 1 or 2 days) are less effective, may be more prone to resistance, and are not recommended.

Drug interactions among the antimalarials are generally inconsequential. The exception is the potentially dangerous exacerbation of halofantrine's effect in prolonging ventricular repolarization (QT prolongation) when given following mefloquine treatment. This may increase the risk of sudden death from ventricular tachyarrhythmias.<sup>99</sup> There is insufficient information on interactions of antimalarials with other drugs (e.g., antiretrovirals).

The global death toll from malaria is rising, and in some areas the increased death toll has been attributed to drug resistance.<sup>100</sup> *P. falciparum* has developed increased resistance to all classes of antimalarial drugs with the exception of the more recently introduced artemisinin derivatives. The other human malarias are generally more drug sensitive, although they have developed antifolate resistance rapidly in some areas. Chloroquine resistance has now developed in *P. vivax* and in Oceania, and in parts of Indonesia is a substantial problem.<sup>101,102</sup> Elsewhere *P. vivax* remains generally chloroquine sensitive.<sup>103</sup> There has been one report of chloroquine-resistant *P. malariae*.<sup>104</sup>

## Classification of Patients for Treatment

It is critical that the care provider determine whether a patient with malaria has uncomplicated or complicated malaria based on clinical, laboratory, or parasitologic findings (see Box 90-2).

## Treatment of Uncomplicated *P. falciparum* Malaria

The goal of treatment of uncomplicated malaria is to cure the infection rapidly and reliably. This means achieving a

**Table 90-3** Summary of Pharmacokinetic Properties of Antimalarial Drugs

<sup>§</sup>Binds to lipoproteins.

<sup>¶</sup>Pregnancy is usually associated with lower drug concentrations and higher treatment failure rates.

**FIGURE 90-5** Pharmacodynamic rationale underlying artemisinin combination treatment (artesunate + mefloquine). Vertical axis (logarithmic scale) shows total number of parasites in the body of an adult with approximately 2% parasitemia. Artesunate given for 3 days covers two asexual cycles and reduces the parasite numbers by a factor of  $10^8$ . Residual parasites ( $10^4$ ) are killed by high concentrations of mefloquine (m to n) (B). If mefloquine alone is used, parasite numbers reduce more slowly and are not eliminated completely for approximately 3 weeks. Thus, in combination treatment, no parasite is exposed to artesunate alone, and only 0.0000001% of the original infecting biomass is exposed to mefloquine alone. (Redrawn from White NJ: Assessment of the pharmacodynamic properties of the antimalarial drugs in vivo. *Antimicrob Agents Chemother* 41:1413–1422, 1997.)

prompt clinical response and then preventing recrudescence. Effective treatment dramatically lowers the risk of progression to severe disease and the additional morbidity associated with treatment failure. Reduction of transmission and prevention of resistance are both important additional considerations for patients treated where malaria is transmitted. In falciparum malaria there is a continuum from mild to severe malaria. Young children with malaria may deteriorate rapidly. Many patients are intolerant of oral medication and require parenteral or rectal administration for 1 or 2 days until they can swallow and retain oral treatment reliably, even though they never show signs of severity. They should receive the same dose regimens as in severe malaria.

Patients without physical signs of severity but who on examination of the blood film are found to have a high parasitemia can be treated with oral antimalarials if their condition can be monitored closely. These patients are at increased risk of developing severe malaria and thus have an increased mortality rate. These patients should be treated with rapidly acting antimalarials such as the artemisinin derivatives or quinine and should be immediately switched to parenteral therapy if signs of severity develop.

After it has been established whether the patient has uncomplicated or complicated malaria, treatment is dependent on the care provider's estimation of how good follow-up will be, whether the patient is returning to a malaria-endemic area, and the availability of specific antimalarials. Several drugs that are recommended in tropical countries (e.g., artemisinin compounds, piperazine) are not available in some temperate countries (e.g., the United States). Drug regimens, including single drugs, with expected cure rates of 100% are used for treating patients in whom there will be good follow-up, such as returning travelers, in nonendemic areas. In malaria-endemic areas, it is now recommended that antimalarials should be used

in combinations, to augment cure rates (which should be at least 90%) and to prevent the emergence of resistance.

Combining two or more antimalarial drugs with different modes of action (and thus drug targets) provides two main advantages: (1) cure rates are usually increased, and (2) in the rare event that a mutant parasite that is resistant to one of the drugs arises de novo during the course of the infection, it will be killed by the other drug. Mutual protection prevents the emergence of resistance.<sup>98</sup> This is the same principle underlying the combination treatment of tuberculosis and HIV infections. Prevention of resistance is necessary to ensure that antimalarial treatment remains highly effective. Both partner drugs in a combination must be independently effective. ACTs are the most rapidly and reliably effective antimalarial drugs, and they have the advantage of inhibiting gametocyte development and thus reducing transmissibility. Artemisinin and its derivatives (artesunate, artemether, artemotil, dihydroartemisinin) produce rapid clearance of parasitemia and rapid resolution of symptoms. They reduce parasite numbers by a factor of approximately 10,000 each asexual cycle,<sup>98</sup> which is more than other antimalarial drugs (which reduce parasite numbers by between 100 and 1000 fold per cycle). Artemisinin is five to ten times less potent than its derivatives and has generally given way to the derivatives. When given alone or in combination with rapidly eliminated compounds (tetracyclines, clindamycin), a 7-day course of treatment with an artemisinin compound is required, but when given in combination with slowly eliminated antimalarial drugs, shorter courses of treatment (3 days) are highly effective.

The artemisinin compounds are active against all four species of malaria parasites infecting humans. There is no confirmed resistance to these drugs, but unless they are given for 1 week they cannot be expected to eliminate asexual erythrocytic stage parasites entirely. The artemisinin derivatives are also remarkably well tolerated. The only significant adverse effect to emerge from extensive clinical trials has been rare ( $\approx 1:3000$ ) type 1 hypersensitivity reactions (manifested initially by urticaria). They also have the advantage from a public health perspective of reducing gametocyte carriage and thus the transmissibility of malaria. This contributes to malaria control.

## Specific Drugs and Drug Regimens

See Table 90-4 for details.

### Atovaquone-Proguanil

This combination of a naphthoquinone and biguanide is effective against all malarias, including multidrug-resistant falciparum malaria. Atovaquone-proguanil is given in a 3-day, once daily regimen. Atovaquone-proguanil is well tolerated with no serious adverse effects. The main problem is the high cost of manufacturing atovaquone. While it continues to be useful for the treatment of travelers and in prophylaxis, it is simply too expensive for large-scale deployment in endemic areas.

### Mefloquine

Mefloquine alone is highly effective against *P. falciparum* from most parts of the world except specific areas of

Southeast Asia (see Table 90-4). Depending on the local sensitivity of the parasite to the drug, a dose of 15 mg base/kg to 25 mg base/kg is administered singly or in two divided doses 8 to 24 hours apart. Children metabolize mefloquine more rapidly than adults and should receive the higher dose. The principal problems with mefloquine are nausea and vomiting in young children, and CNS adverse effects (dizziness, dysphoria, nightmares, and less commonly seizures, encephalopathy, or psychosis). Gastrointestinal intolerance can be reduced by splitting the dose, as mentioned previously.

### Sulfadoxine-Pyrimethamine

Although resistance to sulfadoxine-pyrimethamine (SP) has spread rapidly in recent years (see Table 90-4), compromising

the efficacy of the combination, there are still some areas, notably in West Africa and Pakistan, Afghanistan, and Northwest India, where this combination is very effective. A major advantage of SP is that it is delivered as a single dose and is generally well tolerated.

### Chloroquine

Chloroquine is still the treatment of choice for *P. vivax*, *P. ovale*, *P. malariae*, and the occasional monkey malaria that gets transmitted to humans, but for *P. falciparum* there are now very few places where chloroquine can be relied upon. If one is confident of the response in a locale with presumed chloroquine-sensitive *P. falciparum* (see Table 90-4), then chloroquine can be used. If uncertain, one should choose another antimalarial.

**Table 90-4 Dosage Regimens of Antimalarials for Treatment of Uncomplicated Malaria\***

Type	Malaria Endemic Area	Outside Malaria Endemic Area
<i>P. vivax</i> , <i>P. malariae</i> , <i>P. ovale</i> , known chloroquine-sensitive <i>P. falciparum</i> *	Chloroquine phosphate (1 tablet contains 250 mg salt, equivalent to 155.3 mg base). 10 mg/kg base at 0, 24 hr followed by 5 mg/kg base at 48 hr May be combined with artesunate 4 mg/kg/day for 3 days	Chloroquine phosphate (1 tablet contains 250 mg salt, equivalent to 155.3 mg base). 10 mg/kg base at 0, 24 hr followed by 5 mg/kg base at 48 hr
<i>P. falciparum</i> * known to be sensitive to sulfadoxine-pyrimethamine (SP)	Oral artesunate 4 mg/kg daily for 3 days + pyrimethamine 1.25 mg/kg + sulfadoxine 25 mg/kg (single dose), 3 tablets in an adult	Pyrimethamine 1.25 mg/kg + sulfadoxine 25 mg/kg (single dose) 3 tablets in an adult
<i>P. falciparum</i> * known to be sensitive to amodiaquine	Oral artesunate 4 mg/kg daily for 3 days + Amodiaquine 10 mg base/kg/day for 3 days	Amodiaquine 10 mg base/kg/day for 3 days
<i>P. falciparum</i> known to be sensitive to mefloquine (see Table 90-2 and preceding map for known mefloquine-resistant areas)	Combination only (see below)	Mefloquine 15–25 mg base/kg (single dose or divided into 2 doses given 8–24 hours apart)
	Treatments Effective Everywhere in the World	Treatments Effective in Infections Acquired Anywhere in the World
Chloroquine-resistant <i>P. vivax</i> † and multidrug resistant- <i>P. falciparum</i> *	a. Oral artesunate 4 mg/kg daily for 3 days + mefloquine 25 mg base/kg (15 mg/kg on day 2, 10 mg/kg on day 3) b. Artemether-lumefantrine 1.5/9 mg/kg twice daily for 3 days with food	a. Atovaquone 20 mg/kg/day, proguanil 8 mg/kg/day for 3 days; this should be combined with artesunate in endemic areas b. Quinine 10 mg salt/kg 3 times daily plus doxycycline 3 mg/kg once daily or clindamycin 10 mg/kg twice daily for 7 days

\*In endemic areas, only combination treatments should be used for falciparum malaria, whereas outside the endemic area highly effective monotherapies may be used.

†This refers to truly resistant infections, which are a significant problem only in Oceania and Indonesia, and should not be confused with relapses.

#### General Points

- Pregnancy: Artemisinin and derivatives should not be given in the first trimester of pregnancy. Halofantrine, primaquine, and tetracycline should not be used at any time in pregnancy, and sulfadoxine should not be used very near to term. Mefloquine has been associated with an increased risk of stillbirth in one study but not in another. Atovaquone-proguanil and artemether-lumefantrine have not been evaluated adequately in pregnancy.
- Vomiting may be less likely if the patient's temperature is lowered before oral drug administration.
- Contraindications to mefloquine treatment include use of the drug in the previous 63 days, epilepsy or neuropsychiatric disorder, history of allergy, or following cerebral malaria.
- Short courses of artesunate or quinine (<7 days) alone are not recommended.
- In renal failure the dose of quinine should be reduced by one third to one half after 48 hours, and doxycycline but *not* tetracycline should be prescribed.
- The doses of all drugs are unchanged in children and pregnant women.
- Oral treatment of uncomplicated hyperparasitemic infections should include an artemisinin derivative and be prolonged to minimize the chance of recrudescence, e.g., artesunate loading dose of 4 mg/kg initially followed by 2 mg/kg/day on the following 6 days, in combination with mefloquine, clindamycin, or doxycycline as in the table.
- Patients with *P. vivax* and *P. ovale* infections should also be given primaquine 0.5 mg base/kg (up to 30 mg base) daily for 14 days to prevent relapse (see Table 90-5). In mild G6PD deficiency, 0.75 mg base/kg should be given once weekly for 6 weeks.
- Use of tetracyclines in pregnant women or children under 8 years of age is contraindicated.

## Quinine

Quinine continues to have an important role in malaria treatment. Although there is reduced susceptibility to quinine in parts of Southeast Asia and South America, these reductions are not large and quinine is still effective in these areas. It is still the drug of choice for uncomplicated falciparum malaria in the first trimester of pregnancy regardless of location. Quinine may also be part of second-line treatment regimens, but it is not standard first-line treatment in endemic areas, because it must be given three times daily and is poorly tolerated (bitter taste, nausea, tinnitus, dysphoria, giddiness—a symptom complex termed cinchonism). Poor tolerance reduces adherence to the 7-day regimens needed to achieve high cure rates where there is resistance. In most cases quinine should be combined with either a tetracycline (e.g., doxycycline or tetracycline) or, in children, clindamycin. These antibiotics are given for 7 days. When treating *P. falciparum* from areas with minimal to no quinine resistance, the quinine is generally given for 3 days and the antimalarial antibiotic for 7 days. These combined regimens achieve cure rates of over 90% even in areas of high-level drug resistance. Oral quinine is also often given to complete a full 7 days of treatment following parenteral treatment for severe malaria. Serious adverse effects from oral quinine are unusual in uncomplicated malaria, although hypoglycemia may occur in late pregnancy.

## Treatment with Artemisinin Derivatives and Another Antimalarial

**Artesunate-Mefloquine.** This 3-day combination treatment is effective against all malaria everywhere. The side effects are similar to mefloquine alone (see previous discussion), although early vomiting is reduced by the combination. Fixed-dose regimens are currently being developed that will incorporate the currently recommended doses in a single tablet—4 mg/kg artesunate and 8 mg/kg mefloquine administered daily for 3 days.

**Artemether-Lumefantrine.** This is a 3-day, six-dose regimen. Provided that there is adequate absorption of lumefantrine, this combination would also be expected to be effective against all malaria everywhere. The principal problem with artemether-lumefantrine is variable oral absorption of lumefantrine, which may give rise to treatment failure as a result of inadequate blood concentrations. Absorption of lumefantrine is increased by coadministration with fats (food, milk) and improves as the patient recovers from illness. The combination is remarkably well tolerated and rapidly effective.

**Artesunate-Amodiaquine.** Amodiaquine is more effective than chloroquine against *P. falciparum* in Africa, parts of South America, and Oceania, but not in Asia. Artesunate-amodiaquine is effective in some areas of Africa and South America, but resistance to amodiaquine is increasing. Despite being an “old” drug, there is insufficient information on the pharmacokinetics of amodiaquine, and there are still uncertainties over the true incidence of clinically significant leukopenia, agranulocytosis, and hepatitis when it is used for treatment. All three were observed when amodiaquine was used in antimalarial prophylaxis. Oral amodiaquine is considered more

palatable than chloroquine by young children. The combination is generally well tolerated.

**Artesunate-Sulfadoxine-Pyrimethamine.** A 3-day artesunate-SP combination is well tolerated and effective where sensitivity to SP is retained.

**Chlorproguanil-Dapsone.** This antifol-biguanide combination is given in a 3-day, once daily regimen. It is more effective than SP against antifol-resistant *P. falciparum*, but it is not effective against parasites with the I164L mutation in *Pfdhfr*. Nearly all recent clinical trials have been conducted with 14-day follow-up, so true efficacy is uncertain. Chlorproguanil-dapsone has been well tolerated in clinical trials, although there are some concerns over an increased risk of anemia, probably resulting from dapsone-induced hemolysis. There is insufficient evidence at present to recommend this drug.

**Dihydroartemisinin-Piperaquine.** This fixed combination of dihydroartemisinin and piperaquine is a bisquinoline compound with structural similarities to chloroquine. The treatment course is once daily for 3 days. Piperaquine is considerably more active than chloroquine against resistant *P. falciparum*. It is eliminated slowly (terminal half-life  $\approx$  1 month). The combination was highly effective and well tolerated in large treatment trials in Southeast Asia. It is a promising prospect, but the combination has not yet been evaluated in Africa or the Americas.

## Antibacterials with Antimalarial Activity

Many antibiotics that target protein or nucleic acid synthesis are effective against plasmodia. In general these drugs are relatively weak antimalarials that clear parasitemia slowly if used alone, so they are always combined with a specific antimalarial drug. The main exception is trimethoprim-sulfamethoxazole, which has good antimalarial activity (since trimethoprim has the same mode of action as pyrimethamine) but has to be given for 5 to 7 days. Unfortunately, resistance to SP means resistance to trimethoprim-sulfamethoxazole, and continued use of the antibacterial may also select for SP resistance. Thus, trimethoprim-sulfamethoxazole is not recommended for antimalarial use. The tetracyclines, clindamycin, and sulphonamides are all used in antimalarial treatment. Rifampicin, chloramphenicol, and azithromycin all have significant antimalarial activity. Fosmidomycin is being investigated as an antimalarial. Pending further information, these latter drugs are not recommended for general use.

In the assessment of antimalarial drug efficacy, a follow-up period of at least 28 days is required for rapidly eliminated drugs, but for drugs that are more slowly eliminated (terminal half-life  $>24$  hours; see Table 90-3), the follow-up period should be greater than 42 days.

## Treatment of Malaria Caused by *P. vivax*, *P. ovale*, or *P. malariae*

*P. vivax* is still generally sensitive to chloroquine although resistance is increasing in some areas, notably Oceania, Indonesia, and Peru. Resistance to pyrimethamine is prevalent

in many areas, and SP is consequently ineffective. Proguanil or chlorproguanil are also ineffective in these areas. In general *P. vivax* is sensitive to all the other antimalarial drugs, is more sensitive than *P. falciparum* to the artemisinin derivatives, and is less sensitive to mefloquine (although mefloquine is still effective). In contrast to *P. falciparum*, asexual stages of *P. vivax* are susceptible to primaquine. Thus, chloroquine plus primaquine can be considered a combination treatment. The only drugs with substantial activity against the hypnozoites are the 8-aminoquinolines (primaquine, tafenaquine).<sup>103,106</sup> Recently simple methods for short-term culture of *P. vivax* have been developed, allowing ex vivo assessment of asexual stage drug sensitivity. In vivo assessment suggests that *P. vivax* in East Asia and Oceania is more primaquine-tolerant than elsewhere. There are few recent data on the in vivo susceptibility of *P. ovale* and *P. malariae*. Both are regarded as sensitive to chloroquine, although there is a single recent report of chloroquine resistance in *P. malariae*.<sup>104</sup> Experience indicates that *P. ovale* and *P. malariae* are susceptible also to amodiaquine, mefloquine, and the artemisinin derivatives. The antifol susceptibility is less certain.

For chloroquine-sensitive vivax malaria (i.e., in most places where *P. vivax* is prevalent) the traditional 25 mg base/kg dose of chloroquine is well tolerated and effective. Some have recommended lower total doses, but this is not recommended, since it may encourage the emergence of resistance. Chloroquine is given in an initial dose of 10 mg base/kg followed by either 5 mg/kg at 6, 24, and 48 hours or more commonly as 10 mg/kg on the second day and 5 mg/kg on the third day. The treatment duration can be shortened to 36 hours. It is

also clear that if ACT treatment is given, then *P. vivax* will respond as well as or better than *P. falciparum*. The exception is a regimen containing SP. It appears that *P. vivax* has developed resistance to SP more rapidly than has *P. falciparum*.

There are relatively few data on treatment responses in chloroquine-resistant vivax malaria. Studies from Indonesia indicate that atovaquone-proguanil,<sup>105</sup> halofantrine,<sup>103</sup> mefloquine, and amodiaquine are efficacious. (Atovaquone-proguanil [3 doses over 3 days], mefloquine [25 mg/kg during 1 day], or amodiaquine [30 mg base/kg over 3 days] combined with primaquine should be given for chloroquine-resistant vivax malaria.)

To achieve radical cure of vivax or ovale malaria, relapse must be prevented by giving primaquine.<sup>106</sup> However, the frequency and pattern of relapses vary geographically. It has become clear in recent years that whereas 50% to 60% of *P. vivax* infections in Southeast Asia relapse, the frequency is lower in Indonesia (30%) and the Indian subcontinent (15% to 20%). Thus, the preventive efficacy of primaquine must be set against the prevalent relapse frequency. It appears that the total dose of 8-aminoquinoline given is the main determinant of liver-stage curative efficacy. There is no evidence that the short courses of primaquine widely recommended (such as 5 days of treatment) have any efficacy. Primaquine is given for 14 days. The usually recommended adult dose has been 15 mg base (0.25 mg/kg/day), but in Southeast Asia, particularly Indonesia, and in Oceania, higher doses (0.6 mg base/kg/day) are required, and the CDC now recommends the 0.6 mg/kg dose up to an adult dose of 30 mg base/day (Table 90-5). Primaquine causes abdominal

**Table 90-5** Drugs Used in the Prophylaxis of Malaria as Recommended by the U.S. Centers for Disease Control and Prevention

Drug	Usage	Adult Dose	Pediatric Dose	Comments/Adverse Reactions/Contraindications
Atovaquone/proguanil (Malarone)	Primary prophylaxis* in areas with chloroquine-resistant or mefloquine-resistant <i>P. falciparum</i> Begin 1–2 days before entering endemic area and continue for 7 days after leaving	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride  1 adult tablet orally daily	Pediatric tablets contain 62.5 mg atovaquone and 25 mg proguanil hydrochloride 11–20 kg: 1 tablet 21–30 kg: 2 tablets 31–40 kg: 3 tablets ≥40 kg: 1 adult tablet daily (Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride)	Contraindicated in persons with severe renal impairment (creatinine clearance <30 mL/min) Atovaquone/proguanil should be taken with food or a milky drink Not recommended for children <11 kg, pregnant women, and women breastfeeding infants weighing <11 kg
Chloroquine phosphate (Aralen and generic)	Primary prophylaxis* only in areas with chloroquine-sensitive <i>P. falciparum</i> Begin 1–2 weeks before entering endemic area and continue for 4 weeks after leaving	300 mg base (500 mg salt) orally once per week	5 mg/kg base (8.3 mg/kg salt) orally once per week, up to maximum adult dose of 300 mg base	May exacerbate psoriasis
Doxycycline (Many brand names and generic)	Primary prophylaxis* in areas with chloroquine-resistant or mefloquine-resistant <i>P. falciparum</i>	100 mg orally daily	≥8 years of age: 2 mg/kg up to adult dose of 100 mg/day	Contraindicated in children ≤8 years of age and pregnant women

Continued

**Table 90-5 Drugs Used in the Prophylaxis of Malaria as Recommended by the U.S. Centers for Disease Control and Prevention—Cont'd**

Drug	Usage	Adult Dose	Pediatric Dose	Comments/Adverse Reactions/Contraindications
Hydroxy-chloroquine sulfate (Plaquenil)	Begin 1–2 days before entering endemic area and continue for 28 days after leaving An alternative to chloroquine for primary prophylaxis* only in areas with chloroquine-sensitive <i>P. falciparum</i> Same schedule as chloroquine	310 mg base (400 mg salt) orally once per week	5 mg/kg base (6.5 mg/kg salt) orally once per week, up to maximum adult dose of 310 mg base	See chloroquine comment
Mefloquine (Lariam and generic)	Primary prophylaxis* in areas with chloroquine-resistant <i>P. falciparum</i> Begin at least 2 weeks before entering an endemic area and continue for 4 weeks after leaving A loading dose (1 tablet/day for 3 consecutive days) may be given if the individual is leaving immediately for an endemic area. Such individuals should be counseled and monitored closely for side effects	228 mg base (250 mg salt) orally once per week	5–10 kg: $\frac{1}{8}$ tablet orally once/week 10–20 kg: $\frac{1}{4}$ tablet once/week 20–30 kg: $\frac{1}{2}$ tablet once/week 30–45 kg: $\frac{3}{4}$ tablet once/week >45 kg: 1 tablet once/week The recommended dose of mefloquine is 5 mg/kg body weight once weekly Approximate tablet fraction is based on this dosage Exact doses for children weighing less than 10 kg should be prepared by a pharmacist	Contraindicated in persons allergic to mefloquine and in persons with active depression or a previous history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures Not recommended for persons with cardiac conduction abnormalities
Primaquine	An option for primary prophylaxis* in special circumstances Call Malaria Hotline (770-488-7788) for additional information Begin 1 or 2 days before entering an endemic area, and continue for 3–7 days after leaving	30 mg base (52.6 mg salt) orally daily	0.6 mg/kg base (1.0 mg/kg salt) up to adult dose, orally daily	Contraindicated in persons with G6PD deficiency Contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level Use in consultation with malaria experts
Primaquine	Used for terminal prophylaxis† risk of relapses of <i>P. vivax</i> and <i>P. ovale</i>	30 mg base (52.6 mg salt) orally once daily for 14 days after departure from malarious area Note: The recommended dose of primaquine for terminal prophylaxis has been increased from 15 mg to 30 mg for adults	0.6 mg/kg base (1.0 mg/kg salt) up to adult dose orally once daily for 14 days after departure from malarious area Note: The recommended dose of primaquine for terminal prophylaxis† has been increased from 0.3 mg/kg to 0.6 mg/kg for children	Indicated for persons who have had prolonged exposure to <i>P. vivax</i> or <i>P. ovale</i> , or both Contraindicated in persons with G6PD deficiency‡ Contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level

\*Primary prophylaxis refers to the use of antimalarial drugs to prevent symptoms associated with blood-stage infection; these drugs are taken before, during, and for a period of time after travel in the malaria-risk area.

†Terminal prophylaxis refers to the use of primaquine to lower the risk of relapse from liver-stage infection with *P. vivax* or *P. ovale*. Primaquine is taken after departure from the malaria-risk area.

‡Primaquine is contraindicated in individuals with the severe G6PD deficiency (approximately 5%–10% of normal activity) found in some individuals of Mediterranean and Asian background, but can be given safely to individuals with modest G6PD deficiency (approximately 20% of normal activity) found in individuals of African background.

Available at [www.cdc.gov/travel/malariadrugs2.htm](http://www.cdc.gov/travel/malariadrugs2.htm).

discomfort when taken on an empty stomach; it should always be taken with food.

The inherited sex-linked deficiency of G6PD is associated with some protection against falciparum malaria but increased susceptibility to oxidant hemolysis. The prevalence of G6PD deficiency varies but can be as high as 20%. There are a large number of different genotypes, each with different levels of deficiency. Primaquine is an oxidant and causes variable hemolysis in G6PD-deficient individuals. Fortunately, primaquine is eliminated rapidly, so hemolysis is self-limiting provided no further drug is taken. Screening for G6PD deficiency is not generally available outside hospitals, although rapid stick tests are under development. Many people are unaware of their G6PD status. If a patient is known or suspected (individuals of Mediterranean and Asian descent) to be severely G6PD deficient ( $\approx 5\%$  to  $10\%$  of normal G6PD activity), then primaquine should not be given. For the majority of patients with mild variants ( $\approx 20\%$  of normal G6PD activity), often found in black Africans, primaquine can be given in a dose of 0.75 mg base/kg once weekly for 6 weeks. If significant hemolysis occurs on treatment, primaquine should be stopped. Primaquine is not given during pregnancy because G6PD status of the fetus is unknown. Tafenoquine is a more active and more slowly eliminated 8-aminoquinoline in development. It also causes oxidant hemolysis.

### Treatment of Severe Malaria

Death from severe malaria often occurs within hours of admission to hospital or clinic, so it is essential that therapeutic concentrations of antimalarial drug be achieved as soon as safely possible. This is why a loading dose of certain drugs is essential, particularly quinine, quinidine, and artemether. Nearly all cases of severe malaria result from *P. falciparum* infection. Many patients with malaria, including those with species other than *P. falciparum*, cannot take oral medications initially because of repeated vomiting. They do not fulfil the criteria of severe malaria but do require parenteral (or rectal) administration of antimalarials. In practice if there is uncertainty the patient should be treated as having severe malaria until able to swallow medications reliably. Management of severe malaria comprises four main areas: assessment of the patient, specific antimalarial treatment, adjunctive therapy, and supportive care.<sup>54</sup>

Severe malaria is a medical emergency. The airway should be secured in unconscious patients and breathing and circulation assessed. The patient should be weighed or weight estimated so that drugs, including antimalarials, and fluids can be given on a body weight basis. An intravenous cannula should be inserted, and immediate measurements of blood glucose (stick test), hematocrit, parasitemia (parasite count, stage of malaria parasite development, and proportion of neutrophils containing malaria pigment), and in adults, renal function (blood urea or creatinine) should be taken. The degree of acidosis is an important determinant of outcome; the plasma bicarbonate or venous lactate should be measured if possible. If facilities are available, arterial or capillary blood pH and gases should be measured in patients who are unconscious, hyperventilating, or in shock. Blood should be taken for cross-match, and (if possible) full blood count, platelet count, clotting studies, bacterial culture, and full biochemistry.

Intravenous fluids may then be started. The assessment of fluid balance is critical in severe malaria. Acidotic breathing or respiratory distress, particularly in severely anemic children, often indicates hypovolemia and requires prompt but careful rehydration and, if available, rapid blood transfusion. In adults there is a thin dividing line between overhydration, which may produce pulmonary edema, and underhydration contributing to shock and worsening acidosis and renal impairment. Careful and frequent evaluations of the jugular venous pressure, peripheral perfusion, venous filling, skin turgor, and urine output should be made. When there is uncertainty over the jugular venous pressure, and if nursing facilities permit, a central venous catheter should be inserted and the pressure (CVP) measured directly.

When these immediate measures have been completed, a more detailed clinical examination should be conducted, with particular note of the level of consciousness and record of the coma score. Several coma scales have been advocated. The Glasgow coma scale (GCS) is suitable for adults, and the simple Blantyre modification (BCS) or children's Glasgow Coma Scale (CGCS) for children.<sup>107</sup> Unconscious patients must have a diagnostic lumbar puncture to exclude bacterial meningitis. The opening pressure should be recorded and the rise and fall with respiration noted. CSF should be sent for microscopic analysis, culture, and measurement of glucose, lactate, and protein. After rapid clinical assessment and confirmation of the diagnosis of severe malaria, full doses of antimalarial treatment should be started without delay.

### Specific Antimalarial Treatment of Severe Malaria

Currently four commonly used parenteral drug treatments are recommended for severe malaria: artesunate, artemether, quinine, and quinidine (Box 90-3). Artemotil is also used in some areas. Artesunate, artemether, artemisinin, and quinine have also been formulated for rectal administration. Although chloroquine is available in parenteral formulations and has been used widely in the past, it is no longer recommended because resistance is too widespread to rely on it. Even in a patient considered to need parenteral treatment for *P. vivax*, *P. ovale*, or *P. malariae* infection, it is best to treat for falciparum malaria because there may be a mixed infection. The intramuscular preparation of sulfadoxine-pyrimethamine should not be used to treat severe malaria, since resistance is widespread and responses are slow.

There have been several treatment comparisons in severe malaria, mainly between intramuscular artemether and intramuscular or intravenous quinine.<sup>108</sup> None of these show clear evidence of benefit in terms of survival, although the artemisinin derivatives are simpler to use and safer (principally because of the reduced risk of hypoglycemia). None of the trials was designed to detect less than a 30% reduction in mortality. In an individual patient data analysis of the largest series of prospectively studied patients with severe malaria, 1919 patients were enrolled in randomized comparisons of artemether versus quinine. The mortality in artemether recipients was 136/961 (14%) and in the quinine recipients was 164/958 (17%;  $P=0.08$ ). In the prospectively defined subgroup analysis of adults (largely from Southeast Asia), the mortality difference in favor of artemether was statistically significant.<sup>108</sup> There had been concern that saving the lives of

**Box 90-3** Treatment of Severe Malaria

Artesunate IV: 2.4 mg/kg stat, at 12 and 24 hours, then daily  
or

Artemether IM: initial dose of 3.2 mg/kg followed by 1.6 mg/kg every 24 hours until oral medication is tolerated\*

or

Quinine IV: loading dose (LD) 20 mg salt/kg given over 4 hours, then 10 mg salt/kg given 8 hours after the LD was started, followed by 10 mg salt/kg every 8 hours†

or

Quinine IM: loading dose of 20 mg salt/kg is given as two simultaneous injections in the anterior thigh (10 mg salt/kg in each) after dilution of the quinine in sterile water to a concentration of 60 to 100 mg/mL, maintenance dose of 10 mg salt/kg is given as one IM injection every 8 hours using the same dilution

or

Quinidine IV: 10 mg base/kg infused over 1–2 hours followed by 1.2 mg base/kg per hour by constant infusion.

- Electrocardiographic monitoring necessary‡
- Total treatment duration for all regimens = 7 days
- Once the patient has recovered sufficiently to tolerate oral medication reliably, the parenteral treatment can be discontinued and a second drug should be added, such as doxycycline 3 mg/kg for 7 days, clindamycin 10 mg/kg bid for 7 days, or atovaquone 20 mg/kg/day + proguanil 8 mg/kg/day for 3 days§
- SP single dose can be used if parasites are known to be sensitive

\*Absorption of IM artemether may be inadequate in a subgroup of patients with shock.

†If QTc (on electrocardiogram) is greater than 25% of baseline or exceeds 600 msec or hypotension occurs temporarily reduce or stop infusion.

‡Some authorities recommend a lower dose of 6.2 mg base/kg initially over 1 hour followed by 0.012 mg base/kg/hr.

§Mefloquine should not be used because of the increased risk of post-malaria neurologic syndrome (Mai NTH, Day NPJ, Chuong LV, et al: Post-malaria neurologic syndrome. *Lancet* 348:917–921, 1996).

patients with cerebral malaria might increase rates of neurologic sequelae, but there was no associated increase. There are fewer data for artesunate and very few trials with artemotil (also known as arteether), but since they have a common biologically active metabolite (DHA) they are likely to be at least equivalent to artemether. Indeed, the pharmacokinetic properties of artesunate are superior to those of artemether and artemotil because it is water soluble and can be given either by intravenous or intramuscular injection. Quinidine is more toxic than quinine and should be used only when none of the other effective parenteral drugs are available.<sup>54</sup>

**Pharmacologic Considerations.** In severe malaria it is essential that parasitocidal concentrations of antimalarial drug are attained as soon as safely possible.

- **Artesunate:** Parasitocidal levels are attained immediately following IV injection and within minutes of IM injection. No dose adjustments are needed in liver or renal dysfunction. Artesunate is rapidly hydrolyzed to DHA in vivo. The therapeutic range of DHA is unknown but by extrapolation from in vitro data is exceeded considerably by current dose regimens.

- **Artemether and artemotil:** These oil-based formulations are slowly and erratically absorbed following intramuscular injection (there is no intravenous formulation), and some patients may not achieve parasitocidal concentrations within the first few hours after starting treatment. Absorption is particularly poor in children and adults with poor peripheral perfusion. Artemether is also converted to DHA in vivo, but concentrations of the parent compound exceed those of DHA, so artemether contributes the majority of antimalarial effect in vivo. No dose adjustments are needed in liver or renal dysfunction.

- **Quinine:** A full loading dose (20 mg quinine dihydrochloride salt/kg) should always be given irrespective of the degree of vital organ dysfunction unless there is clear evidence that the patient has already received adequate quinine treatment (>40 mg salt/kg in the past 48 hours). For quinine there is considerable variability in apparent volume of distribution, so the full loading dose is necessary to ensure that the majority of patients do have adequate blood concentrations. In the past there was too much concern over the dangers of potential quinine toxicity and insufficient concern over the dangers of undertreatment in severe malaria. The risk-benefit ratio changes as treatment progresses. The majority of deaths from malaria occur within the first 48 hours following admission to hospital; undertreatment may have fatal consequences. In practice, quinine toxicity in the first 24 hours of treatment is rare. The maintenance dose studied in Asia has been 10 mg/kg every 8 hours, but the dose interval in Africa has sometimes been 12 hours. After 48 hours of treatment if there is no clinical improvement in severe malaria, or if the patient is in acute renal failure, to avoid continued accumulation to potentially toxic concentrations. The therapeutic range has not been well defined, but total plasma concentrations of between 8 and 15 mg/L are thought to be safe and effective. Toxicity is increasingly likely with plasma concentrations over 20 mg/L (free quinine >2 mg/L).

Quinidine is more toxic than quinine. Both hypotension and prolongation of ventricular repolarization (QTc interval) are common when parenteral quinidine is used in the treatment of severe malaria. There have been only two small studies of quinidine in severe malaria so dose recommendations rest on limited information. Ideally patients receiving quinidine should have careful cardiovascular monitoring and frequent measurement of plasma concentrations to guide dosing. As with quinine, the dose should be reduced if there is no clinical improvement within 48 hours. Currently an 8 hour interval is recommended. Dose reduction by 1/3 to 1/2 is recommended.

**Where Parenteral Treatment Cannot Be Given.** In most areas of the rural tropics, severe malaria occurs far from medical attention. Since delay in starting treatment can have fatal consequences, rectal formulations of artemisinin have been developed. These can be given by village health workers pending transfer to a facility where parenteral treatment and supportive can be given.<sup>109–111</sup>

## Supportive Care

Patients with severe malaria require intensive nursing in an intensive care unit if possible. Following the initial assessment and commencement of antimalarial treatment, clinical observations should be made as frequently as possible. These should include recording of vital signs, with an accurate assessment of respiratory rate and pattern, assessment of the coma score, and urine output. The blood glucose should be checked, with rapid stick tests every 4 hours if possible, particularly in unconscious patients. Convulsions should be treated promptly with anticonvulsants such as intravenous or rectal diazepam or intramuscular paraldehyde.

Each patient's fluid requirements should be assessed individually. Adults with severe malaria are vulnerable to fluid overload and the physician treads a narrow path between underhydration, and thus worsening renal impairment, and overhydration, with the risk of precipitating pulmonary edema. If the patient becomes oliguric ( $<0.4$  mL of urine/kg/hr) despite adequate rehydration and the blood urea or creatinine are rising or already high, fluids should be restricted to replace insensible losses only. Children, on the other hand, are more likely to be dehydrated and may respond well to a rate-controlled bolus of fluid. The fluid regimen must also be tailored around infusion of the antimalarial drugs. The CVP should be maintained between 0 and 5 cm. If the venous pressure is significantly elevated (usually because of overenthusiastic fluid administration), the patient should be nursed with the head at 45 degrees and intravenous furosemide given if necessary.

If blood glucose is less than 4 mmol/L, then a 10% glucose infusion should be started following saline replacement; if it is less than 2.2 mmol/L, then hypoglycemia should be treated immediately (0.3 to 0.5 g/kg glucose or 5 mL/kg 10% dextrose as an IV bolus). Hypoglycemia should be suspected in any patient who deteriorates suddenly. Stick tests may overestimate the frequency of hypoglycemia, so laboratory confirmation may be necessary.

Patients with acute pulmonary edema should be nursed upright and given oxygen, and the right-sided filling pressures should be reduced with whichever treatments are available (loop diuretics, opiates, venodilators, venesection, hemofiltration, dialysis). The right-sided pressure should be reduced to the lowest level compatible with an adequate cardiac output. Positive pressure ventilation should be started (if available) if the patient becomes hypoxic.

Less than 5% of patients with severe malaria develop clinically significant DIC. These patients should be given fresh blood transfusions and vitamin K. Patients with secondary pneumonia should be given empirical treatment with a third-generation cephalosporin unless admitted with clear evidence of aspiration, in which case penicillin or clindamycin is adequate. Children with persistent fever despite parasite clearance may have a systematic *Salmonella* infection, although in most cases of persistent fever after parasite clearance no other pathogen is identified. Urinary tract infections are common in catheterized patients. Antibiotic treatments should depend on likely local antibiotic sensitivity patterns.

## Severe Malaria in Pregnancy

Pregnant women in the second and third trimesters are more likely to develop severe malaria than are other adults,

often complicated by pulmonary edema and hypoglycemia.<sup>54</sup> Maternal mortality from severe malaria approximates 50%, which is higher than in nonpregnant adults. Fetal death and premature labor are common. The role of early cesarean section for the viable live fetus is unproved but is recommended by many authorities. Obstetric advice should be sought at an early stage, the pediatricians alerted, and the blood glucose checked frequently. Hypoglycemia should be expected and is often recurrent if the patient is receiving quinine. The antimalarial drugs should be given in full doses (Boxes 90-3 and 90-4). Severe malaria may also present immediately following delivery. Postpartum bacterial infection is a common complication in these cases. Falciparum malaria has also been associated with severe mid-trimester hemolytic anemia in Nigeria. This often requires transfusion in addition to antimalarial treatment and folate supplementation.

## Follow-up Treatment of Severe Malaria

When the patient with severe malaria has recovered sufficiently, oral medication should be substituted. Infections resulting in severe malaria are more likely to recrudescence than milder infections. They are a potentially important source of resistance, and it is correspondingly important that a full course of curative treatment be completed. There has been only one comparative evaluation of consolidation treatments and no studies in which recrudescence rates were documented. A randomized comparison of oral quinine plus SP versus mefloquine (following parenteral artemether or quinine) was

### Box 90-4 Treatment of Uncomplicated Malaria in Pregnancy

Quinine 10 mg salt/kg tid for 7 days. This should be combined with clindamycin (10 mg/kg bid) for 7 days in the second and third trimesters of pregnancy\*

or if the infection is known to be from an area with SP sensitivity, pyrimethamine 1.25 mg/kg + sulfadoxine 25 mg/kg (single dose) 3 tablets in an adult

or if the infection is known to be from an area with chloroquine sensitivity to *P. falciparum* or for infections with *P. vivax*, *P. ovale*, or *P. malariae*

Chloroquine Phosphate (1 tablet contains 250 mg salt, equivalent to 155.3 mg base)\* 10 mg/kg base at 0, 24 hr followed by 5 mg/kg base at 48 hr

Artemisinin derivatives should not be used in the first trimester of pregnancy. In the second and third trimesters of pregnancy, artesunate (2 mg/kg/day for 7 days) may be given with one of the other drugs

The role of mefloquine in the treatment of malaria in pregnancy remains uncertain; in one large study, there were no adverse effects<sup>†</sup> but in another, there was an increased risk of stillbirth<sup>‡</sup>

\*Quinine has been shown to be safe in all trimesters. There is no evidence for an increased risk of abortion, stillbirth, or congenital abnormality, but in the third trimester there is an increased risk of iatrogenic hypoglycemia with quinine treatment.

†Steketee RW, Wirima JJ, Slutsker L, et al: treatment and prevention in pregnancy: Indications for use and adverse events associated with use of chloroquine or mefloquine. *Am J Trop Med Hyg.* 55(1 Suppl): 50-56, 1996.

‡Nosten F, Vincenti M, Simpson JA, et al: The effects of mefloquine treatment in pregnancy. *Clin Infect Dis*, 28:808-815, 1999.

conducted in Vietnam. Mefloquine recipients had a significantly increased risk of neuropsychiatric reactions (absolute risk of 5% compared with 0.1% to 1% in uncomplicated malaria). In a nonrandomized study of doxycycline pharmacokinetics following severe malaria, it was suggested that the current dose regimen (3 to 3.5 mg/kg/day) may be insufficient.

Current practice is to continue the same drug orally as given parenterally to complete 7 days of treatment. In nonpregnant adults, doxycycline is added to either quinine, artesunate, or artemether also to complete 7 days of treatment. Doxycycline is preferred to other tetracyclines because it can be given once daily and does not accumulate in renal failure. Since doxycycline only starts when the patient has recovered sufficiently, the doxycycline course finishes after the quinine, artemether, or artesunate course. Where available and affordable, clindamycin may be substituted in children and pregnant women because doxycycline cannot be given to these groups. In areas where SP is still effective, it is often given as consolidation therapy. Although following parenteral treatment with a full course of artemisinin combination treatment (i.e., artesunate-amodiaquine, or artemether-lumefantrine) is theoretically a good alternative, this has not been evaluated in clinical trials.

## PREVENTION AND CONTROL

### Malaria Prevention in Visitors to Malaria-endemic Areas

Malaria poses a health risk to visitors to malaria-endemic regions. Annually millions of travelers from nonendemic countries travel to areas where there is a malaria risk. As well, many residents of nonendemic regions of countries that have areas of malaria risk are at risk of infection during short-term visits. Prevention and suppression of infection are far more effective than reliance on treatment of malaria illness in these visitors, owing to the unpredictability of the availability and quality of medical care in many settings. The prevention of infection and disease relies largely on the prophylactic use of malaria drugs, and the specific regimens are outlined in Table 90-5.

Several general principles should guide the protection of visitors to regions with risk of malaria transmission. First and foremost, individuals should be protected optimally if there is any risk, since a single infected mosquito bite may result in a fatal malaria infection. If the area to be visited has any *P. falciparum*, the choice of drug for prevention should be based on an assumption of drug resistance unless the travel is to Haiti or Central America. Finally, while the use of efficacious drugs (chemoprophylaxis) can afford a high degree of protection, it is important for visitors to use mosquito protection, including bed nets and repellents, and to be aware of how to secure safe and effective medical attention in the event of a potential malaria illness.

Malaria drugs for use in prevention among visitors have several distinct modes of action. Most drugs used for chemoprophylaxis are only blood schizonticides (only killing blood-stage parasites). These include chloroquine and other 4-aminoquinolines and mefloquine. These drugs do not prevent primary infection of the liver but kill parasites once they erupt from the liver and invade erythrocytes, thereby preventing disease progression.

A limited number of drugs have activity against parasites developing in hepatocytes and are termed tissue schizonticides

and causal prophylactic drugs. The 8-aminoquinolones, primaquine<sup>112</sup> and the longer acting tafenaquine<sup>113</sup> (in development), kill liver-stage parasites. Primaquine has only modest activity against the asexual erythrocytic stages, and tafenaquine probably has more activity against blood stages. The best activity of atovaquone/proguanil,<sup>114</sup> tetracycline, and doxycycline is against the asexual erythrocytic stages (blood schizonticides), but they all have some activity against *P. falciparum* liver stages, and atovaquone/proguanil may have activity against *P. vivax* liver stages. Atovaquone/proguanil<sup>114</sup> and doxycycline are considered first-line drugs. Primaquine is now being recommended more often for chemoprophylaxis because it can be taken on the day of arrival in a malarious area and for only a few days afterward<sup>112,115</sup> and is much less expensive than atovaquone-proguanil, which has a similar dosing regimen. The specific recommendations of the CDC are outlined in Table 90-5.

### Drug Safety and Contraindications

The risk of being infected during visits to malaria-endemic areas is highly variable but is low in the vast majority of settings. Furthermore, most travelers are healthy, and avoidance of travel and risk also is an option. Consequently, drugs used for chemoprophylaxis need to be well tolerated and should not pose a substantive health risk. The current standard chemoprophylactic drugs are within acceptable levels of safety, yet each has a spectrum of potential and non-life-threatening adverse side effects that must be appreciated by travelers and their medical advisors. The CDC<sup>116</sup> and WHO have excellent information on these risks and advice for special populations.

Pregnant women and young children pose special challenges in the chemoprophylactic use of drugs. For several drugs there are specific contraindications for these populations (e.g., tetracycline). Licensure of most drugs by the FDA does not generally address the safety of drugs during pregnancy and in infancy (e.g., mefloquine); consequently, their use for short-term travel needs to be considered carefully. Ancillary prevention methods (bed nets) and the delaying of travel should always be considered.

### Malaria Drug Prophylaxis for Residents of Malaria-endemic Areas

The routine use of malaria drugs for suppressing malaria disease lost favor during the 1970s to 1980s due principally to the presumption that the use of drugs on a mass basis at subtherapeutic doses would foster the intensification of drug resistance to valuable therapeutic drugs, notably chloroquine.

In recent years selective use of malaria drugs in a preventive mode but at therapeutic doses (intermittent preventive treatment, or IPT) has been documented to be highly effective in controlling the risk of death and severe anemia in pregnant women and infants (see later).

### Malaria Control in Malaria-endemic Areas

During the past decade there has been a renewal in the global commitment to control the enormous health and economic burden that malaria extracts. Underlying this resurgence is a highly cost-effective set of malaria control

interventions that, despite technical limitations such as drug resistance, have been demonstrated to control both malaria transmission and disease. While the treatment of malaria illness remains a constant component of malaria control, prevention has become the predominant cost-effective approach. The major challenge to the control of malaria has been the development of effective program delivery systems to attain and sustain high population coverage.

Based on malaria epidemiology and the capacity of local health system infrastructures to deliver malaria control interventions, there are currently several distinct settings for malaria prevention and control efforts. In areas where malaria transmission is either highly seasonal or of low intensity, principally in the Indian subcontinent and Southeast Asia and most of the Americas, malaria control focuses around the prompt and effective treatment of malaria illness and selective use of antimosquito measures. In many of these areas there is a continuation of control methods developed during the malaria eradication programs of 1950 to 1975, with the use of the indoor spraying of residual insecticides (currently very limited use of DDT and more typically use of less environmentally threatening chemicals) to interrupt malaria transmission.

Malaria control programming and funding has in recent years focused on developing national level programs to stem the health and economic burden in Africa. Based on WHO and Roll Back Malaria guidance, the following are the key malaria control and prevention interventions advocated for the Africa region.

### Insecticide-treated Nets

Based on evidence from five randomized controlled trials and population-based program effectiveness studies in different malaria transmission settings, insecticide-treated nets (ITNs) can reduce the number of under-5 deaths from all causes by about 20% and clinical episodes of malaria by about half<sup>117</sup> (Fig. 90-6). Since malaria causes approximately 20% of under-5 mortality in Africa, the protective efficacy of nets on malaria-specific mortality in children less than 5 years of age is probably at least 80%, in the range of the protective efficacy of most childhood vaccines.<sup>118,119</sup> Recent evidence shows that ITNs protect not only those who sleep under them but also those in

**FIGURE 90-6** Children sleeping under an insecticide-impregnated bed net. (Courtesy of C. Campbell.)

the same dwelling and those living nearby. Current ITNs need to be re-treated after three washes, or at least once a year. ITNs are less effective in parts of Asia, where the main malaria vectors bite outdoors early in the evening.

### Indoor Residual Spraying

Indoor residual spraying (IRS) has been a highly effective intervention in many parts of the world, and in particular in the Americas, in Asia and in Southern Africa. IRS, through its house-to-house, publicly funded and managed approach can achieve very high coverage and thus major impact on malaria disease burden. IRS programs are of limited application in most rural areas with stable malaria endemicity, especially those where there has been no tradition of managing programs of such logistic complexity.<sup>120</sup>

### Intermittent Preventive Treatment

Intermittent preventive treatment (IPT) is the preferred approach to reduce the adverse consequences of malaria during pregnancy; it involves the administration of full curative treatment doses of an effective antimalarial drug, preferably single-dose, at predefined intervals during pregnancy, beginning in the second trimester after quickening. IPT with SP is highly effective in reducing the malaria parasite load, thus reducing severe anemia in the mother and lowering the proportion of low-birth-weight babies.<sup>121,122</sup> There is uncertainty how to deploy IPT in the increasing areas of SP resistance and whether IPT should be deployed in low transmission settings.

### Prompt and Effective Case Management of Malaria Illness

The prompt recognition that a febrile illness could potentially be caused by malaria is the key to limiting the risk of progression to severe or fatal disease. In most of the malaria-endemic world, malaria is self-diagnosed and treated; many episodes of fever not caused by malaria are therefore self-treated with antimalarials. Standard microscopy—and increasingly, rapid diagnostic tests in certain settings—allow for a proper diagnosis of malaria and increase the chances that antimalarial drugs are used for the correct purpose and not simply in response to an unspecified fever episode.

While drug efficacy should be the principal determinant of which drugs are used to treat malaria infections, in many settings there are many drugs of variable or undocumented quality, and a majority of malaria drugs come from commercial outlets without the advice of a health care provider.

### Program Goals for Malaria Control

Global eradication of malaria transmission is not a realistic goal for the foreseeable future. However, elimination of malaria transmission in some regions (mainly in areas of Asia and the Americas) could be accomplished with increased and sustained funding and political priority. For the Africa region, the Abuja Ministerial Summit in 2000 established malaria program targets to be obtained by the end of 2005. These program coverage targets are as follows:

- 60% of malaria patients have access to appropriate treatment within 24 hours of onset of symptoms

- 60% of children and pregnant women are protected by ITNs
- 60% of pregnant women have access to appropriate presumptive IPT for malaria.

Pilot malaria program trials have demonstrated that with integrated application of the malaria control interventions it is possible to reduce malaria deaths and economic impact by 60% to 80%.<sup>1,2</sup>

### Development of New and More Effective Malaria Control and Prevention Tools

Although there are highly efficacious interventions for malaria control and intervention, continued emphasis on the development of new and more efficacious methods is required.

#### Response to Drug Resistance and the Development of New Malaria Drugs

Since the early 1960s, resistance to an increasingly broad spectrum of malaria drugs has been documented in *P. falciparum* (see Table 90-2).

Resistance has had a profound impact on malaria control and prevention efforts globally. Alternative drugs to chloroquine have proved to be considerably more expensive and have safety profiles that limit their programmatic use in some populations.

In response to the continued spread of drug resistance, WHO has developed strategies in an attempt to slow the development and spread of drug resistance. Currently it is recommended that areas affected by resistance to one or more of the standard malaria drugs should deploy combination therapy, that is, the use of two or more efficacious drugs that have distinct modes of action. Further, based on experience in Southeast Asia, artemisinin-containing combination therapy is preferred.

The cost of ACT therapy is a major challenge to broad implementation of this policy guidance, especially in Africa.

The development of novel malaria drugs has received renewed attention in recent years, notably under the guidance of several multinational initiatives such as the Medicines for Malaria Venture ([www.mmv.org](http://www.mmv.org)), a public private partnership devoted to malaria drug development, and the continued activities of institutions such as Walter Reed U.S. Army Institute of Research and WHO/TDR ([www.who.int/tdr](http://www.who.int/tdr)). There are promising leads, but cost and the long lead time required to move efficacious compounds to licensure remain serious impediments to the control and prevention of malaria globally.

#### Development of Malaria Vaccines

Malaria vaccines could benefit those living wherever there is malaria and travelers to these areas. The primary goal, however, must be to prevent the enormous numbers of deaths and cases of severe malaria in infants and young children in Africa caused by *P. falciparum*. Thus, most malaria vaccine development efforts are focused on *P. falciparum*.

There are no commercially available vaccines for human parasites. Parasites present a greater challenge than do the viruses and bacteria for which we have vaccines because they are more complex. They have much larger genomes coding

for more proteins. They have multistage life cycles in which they express many different proteins at different times (Fig. 90-7). As a result, protective immune responses against the extracellular sporozoites that enter with the bite of a mosquito may have no effect on the parasites that later emerge from the liver and infect red blood cells (the asexual erythrocytic stage merozoites). The *P. falciparum* parasite in particular has enormous variability in its proteins. These characteristics are critical to the parasite's survival because they enable it to evade host immune defenses. They also mean that a vaccine containing just a single sequence of a single protein, or a few proteins, may fail to have a large, sustainable impact on the disease. A truly effective malaria vaccine may need to induce both antibody and T-cell responses. Antibodies have the potential to block sporozoites as they enter the body (see Fig. 90-7) but have to act within minutes to block entry into the liver. They can also prevent infection of red blood cells, help destroy those that are already infected, and prevent infection of mosquitoes. T cells have the potential to kill infected liver cells, thereby controlling and even eliminating infection. Both types of responses may have to be directed against multiple different proteins, at different stages of the complex parasite life cycle, and at the same time.<sup>123-126</sup> If so, malaria vaccine developers face a technical problem that has never been solved.

Scientists attempting to develop a malaria vaccine keep two observations in mind. The first is that most malaria-associated deaths and severe disease in sub-Saharan Africa occur in infants, young children, and pregnant women. Adolescents and adults rarely develop severe disease or die after repeated infections with *P. falciparum*. They have presumably developed natural immunity that limits parasite replication and severe forms of malaria but does not prevent infection resulting in milder symptoms.<sup>41</sup> Pregnant women, especially with their first child, apparently lose this immunity. This observation has led to the idea that a vaccine would be worthwhile even if it only limited the severity of disease for those most at risk without preventing infection or moderate disease. Such a vaccine would probably not be useful for travelers. The second observation is that when volunteers are exposed to more than a thousand bites from *P. falciparum*-infected *Anopheles* mosquitoes that have been irradiated to weaken the sporozoites they carry, they develop protective immunity against multiple strains of *P. falciparum*. If these volunteers are exposed to normal sporozoites, more than 93% are completely protected against developing erythrocytic stage infection.<sup>127</sup> This is the strongest evidence that development of a highly effective malaria vaccine is possible, and accordingly there are efforts to develop vaccines that prevent all infections with *P. falciparum* in a majority (>85%) of recipients.<sup>128</sup>

There are three main strategies by which it may be possible to achieve one or both of the preceding goals. The first is to create vaccines that counter sporozoites as they enter the body and invade and reproduce in the liver (pre-erythrocytic stage vaccines). These have the potential to limit or prevent infection altogether. The second is to limit parasite invasion of erythrocytes and subsequent multiplication and pathologic effects (asexual erythrocytic stage and antitoxin vaccines). Such vaccines would limit only severe disease—they would not prevent infection or mild disease. The third strategy is to prevent the spread of viable parasites to other people with “transmission-blocking vaccines.” These stimulate the production of antibodies that are ingested with the parasite

**FIGURE 90-7** Schematic of the life cycle of *P. falciparum* with indication of which immune responses can affect which stage of the life cycle. (From Hoffman SL [ed]: *Malaria Vaccine Development: a Multi-Immune Response Approach*. Washington, DC, ASM Press, 1996. Courtesy of the American Society of Microbiology.)

and destroy the parasite within the vector's gut (see Fig. 90-7). It may be necessary to combine all three strategies to have maximum success. Current vaccine candidates in clinical trials, however, contain just one or a few proteins. In contrast, the protective immune responses elicited by natural exposure to malaria or by immunization with radiation-attenuated sporozoites could be directed at many—perhaps hundreds or even thousands—of the proteins encoded by the 5300 genes in the *P. falciparum* genome.

According to WHO in 2004 more than 70 subunit malaria vaccine candidates are in different stages of development.<sup>129</sup> Despite these efforts only one *P. falciparum* protein, the *P. falciparum* circumsporozoite protein (PfCSP),<sup>130</sup> has been repeatedly evaluated in clinical trials and shown to provide complete protection in a portion of volunteers. The protein was discovered in 1979 by the Nussenzweig group, shown to be protective in mice in 1980, and first shown to protect humans as a vaccine in 1987. The lead candidate based on this protein is called RTS,S/AS02A, and it protects 40% to 45% of nonimmune volunteers against experimental challenge with *P. falciparum* for 2 to 3 weeks.<sup>131,132</sup> In 1- to 4-year-old children in Mozambique during 6 months it reduced the incidence of new clinical attacks of malaria by 22.6%, new *P. falciparum* infection

by 10.4%, and the incidence of severe disease by 58%.<sup>133</sup> In addition to the modern subunit vaccine approaches, there is a major effort to develop a nonreplicating, metabolically active whole sporozoite *P. falciparum* vaccine.<sup>128</sup>

It currently costs \$0.5 billion to \$1 billion to bring a vaccine to market. There are large numbers of vaccine candidates in preclinical and clinical development, and many more candidates are likely to enter efficacy field trials in the next 5 years. Furthermore, emerging genomic and proteomic studies of *P. falciparum* will lead to the development of even more candidate vaccines.<sup>134</sup> It will unquestionably take creative public-private partnerships to bring a malaria vaccine to the infants who need it most. Despite the great need, it will be a number of years before a malaria vaccine is widely used to successfully prevent the morbidity and mortality of *P. falciparum* in the 20 to 25 million infants born annually in sub-Saharan Africa.

# Babesiosis

SAM R. TELFORD III  
JAMES H. MAGUIRE

## INTRODUCTION

Babesiosis, a tick-borne malaria-like zoonosis, appears to have plagued humans since antiquity in its veterinary form. "Behold, the hand of the Lord is upon thy cattle. ... [They] shall be afflicted with a grievous murrain" (Exodus 9) may refer to red-water fever due to *Babesia bovis*. Human babesiosis has been reported mainly from Europe and the eastern or western United States and, recently, from subtropical areas such as Taiwan, the Canary Islands, and South Africa. The prevalence of babesiosis afflicting domestic animals in tropical regions suggests that human infection is not rare in the tropics and perhaps is mistaken for falciparum malaria.<sup>1</sup>

## AGENT

### History and Taxonomy

The genus *Babesia* is named after the Romanian bacteriologist Victor Babes, who in 1888 attributed "hemoglobinuric fever" of cattle to inclusions he detected within erythrocytes. Subsequently, these organisms were determined to be distinct from plasmodia and other coccidia and were assigned to the suborder Piroplasmidea on the basis of their erythrocytic localization, replication by budding rather than schizogony, and inability to produce hemozoin.<sup>2</sup> Currently, they are classified as apicomplexans of the order Piroplasmidora and family Babesiidae.<sup>3</sup> More than 100 species of *Babesia* have been described from domestic and wild mammals on the basis of morphology and life cycle.<sup>3</sup> Molecular taxonomic analyses suggest that there is even greater diversity than what has previously been recognized.<sup>4-7</sup> The powerful new methods of molecular phylogenetics will eventually stimulate the development of a new classification for the piroplasms, but such an action is currently premature inasmuch as life cycle information is lacking for a large proportion of currently recognized taxa.

### Life Cycle

In 1893, Theobald Smith<sup>8</sup> described the life cycle of *Babesia bigemina*, the agent of bovine red-water fever, and in doing so demonstrated for the first time transmission of an infectious agent by arthropods. All piroplasms for which the life cycle has been described require a tick as the definitive host. On ingestion of infectious blood from a vertebrate host, babesiae undergo syngamy and replicate in the intestinal

epithelium of the tick vector and develop further in the salivary glands, ovaries, and other tissues. Sporozoites in the salivary glands are deposited in the skin of a vertebrate host during the tick's blood meal. Because of transstadial transmission, ticks infected as larvae generally remain infected as nymphs and adults. Transovarial transmission in the tick has been documented for some species, such as *B. bigemina*, but not for others, such as *Babesia microti*; such a major life history difference has long been considered to represent a significant phylogenetic divergence.

The common belief that sporozoites enter erythrocytes directly (no pre-erythrocytic phase) has not been critically examined. Exoerythrocytic forms have been demonstrated in

\**Ixodes* species include *I. scapularis* and *dammini* (for *B. microti*), *I. ricinus* (for *B. divergens*), and probably *I. granulatus* and *ovatus* (for *B. microti* in Asia)

the lymphocytes with *Babesia equi* and the closely related *Theileria* species<sup>9,10</sup> and may occur in infections with *B. microti*.<sup>10</sup> The process by which the extracellular merozoite invades erythrocytes (induced endocytosis) is similar to that of the plasmodia. In the rat babesia, *Babesia rodhaini*, complement appears to facilitate invasion by modification of either the red blood cell surface or that of the merozoite.<sup>11</sup>

Following entry into the erythrocyte, the pear-shaped trophozoites (piroplasms) replicate by asynchronous budding rather than by schizogony, as occurs in malarial parasites. During replication, double-membraned segments develop and pinch off from the parental piroplasm, resulting in both asexually reproducing merozoites and “accordion”-like non-replicating sexual parasites (gametocytes<sup>12</sup>). Asexual forms appear as simple rings, pairs, or tetrads and are difficult to distinguish from sexual stages by light microscopy.

## EPIDEMIOLOGY

Two major epidemiologic patterns of human babesiosis are apparent. The first involves splenectomized or otherwise compromised persons and diverse babesiae, some of which have been distinguished only by molecular phylogenetic methods. A bovine-infecting species identified as *Babesia bovis* (perhaps conspecific with *Babesia divergens*<sup>13</sup>) was the cause of the first convincingly documented case of human babesial infection in 1957. The patient, a 33-year-old splenectomized farmer living in Yugoslavia and who had been exposed to cattle, died as a result of hemolytic anemia, hemoglobinuria, and renal failure.<sup>14</sup> Since then, more than two dozen sporadic cases have been reported from Ireland, Yugoslavia, France, the British Isles, Spain, the Canary Islands, Portugal, Germany, Sweden, and Russia.<sup>15</sup> All were severe and many were fatal despite treatment. The vector is *Ixodes ricinus*, which also transmits Lyme disease, granulocytic ehrlichiosis, and tick-borne encephalitis; to date, the only known reservoirs of *B. divergens* other than ticks are cattle and reindeer.

In 1992, a splenectomized man living in rural Missouri and with unspecified exposure history died of infection with a parasite closely related to if not conspecific with *B. divergens*, designated MO-1.<sup>16</sup> A splenectomized Kentucky resident who had been exposed while hunting rabbits recovered from a similar infection in 2001<sup>17</sup>; sequencing of a large portion of the 18S rDNA demonstrated virtual identity (99.8%) with sequences of bovine-derived *B. divergens* and 100% identity with an agent maintained among cottontail rabbits by *Ixodes dentatus*.<sup>18</sup> Accordingly, this infection appears to be due to exposure to *I. dentatus* or to rabbit blood. A third case was reported in a splenectomized resident of Washington state.<sup>19</sup> Although the degree of DNA sequence similarity between the U.S. *divergens*-like parasites and the European cattle parasites is within that which might be expected due to geographic variation of a single species, the former fails to propagate by subinoculation into gerbils, whereas the latter readily does so. Accordingly, molecular phylogenetic data must be complemented with additional life history data, in particular cattle inoculation to demonstrate the development of typical bovine red water, prior to concluding identity. Although European “*divergens* babesiosis” has heretofore been solely attributed to infection by *B. divergens*, molecular analysis suggests that another closely related babesia, designated EU-1<sup>20</sup> and perhaps

representing *Babesia capreoli* (an agent maintained by *I. ricinus* among red or roe deer<sup>21,22</sup>), also parasitizes humans and could be mistaken by inexperienced microscopists for *B. divergens* infection. Thus, it appears that *divergens* babesiosis may be due to diverse parasites that are geographically widespread.

A variation on this epidemiologic pattern has emerged along the Pacific Coast of the United States. The agent WA-1 is closely related by DNA sequencing to the canine pathogen *Babesia gibsoni*.<sup>23,24</sup> CA-type (DNA sequences designated CA-1, CA-2, etc.) agents<sup>25</sup> are most closely related to parasites of mule deer and bighorn sheep.<sup>6</sup> Both agents cause a similar disease and appear morphologically indistinguishable on blood smears, with abundant Maltese-cross forms within parasitized erythrocytes. Of seven reported cases of WA-1 or CA-type babesiosis, four occurred among people who had undergone splenectomy, and one involved an apparently healthy 41-year-old man. The others were transfusion-induced cases involving a spleen-intact elderly man with multiple medical problems<sup>26</sup> and a premature infant.<sup>27</sup> It appears that most infections are subclinical because surveys have shown a seroprevalence of 3.5% to 20% among people with exposure in rural and semirural areas of California.<sup>28</sup> As with *B. divergens*, splenectomized or otherwise compromised individuals appear to suffer pathology; cases are sporadic.

The second major epidemiologic pattern is that of endemic infection due to the widely distributed rodent piroplasm *B. microti*.<sup>29</sup> The risk of human infection with this organism is not increased in the absence of a spleen, although infected people without spleens are at high risk of becoming severely ill. The global distribution of *B. microti* parallels that of *Borrelia burgdorferi* and other agents transmitted by ticks in the *Ixodes persulcatus* species complex.<sup>30</sup> Human babesiosis due to *B. microti* has been reported from Taiwan and Japan.<sup>31,32</sup> A report of *B. microti* babesiosis in a Swiss patient<sup>33</sup> should be considered inconclusive: The photomicrographs from the patient's blood smear appear to demonstrate platelets as opposed to parasites, and associated laboratory tests (serology and polymerase chain reaction) were conflicting. It is likely, however, that *B. microti* is zoonotic in Europe: A mild self-limited febrile case in a German forest worker was anecdotally reported in the caption of a photomicrograph of this parasite from this patient's blood smear.<sup>34</sup>

In the United States, *B. microti* babesiosis remains limited to the terminal moraine islands of New York, Massachusetts, and Rhode Island and focal areas in Connecticut, New Jersey, Wisconsin, and Minnesota.<sup>35</sup> Because most cases are asymptomatic or mildly symptomatic, the incidence is difficult to estimate and differs from year to year due to fluctuations in the densities of the rodent reservoir and tick vectors. Although there have been only several hundred reported cases of symptomatic infection with *B. microti* since the first reported case in 1969, serologic surveys indicate that in highly endemic areas as many as 9% to 21% of people have been infected.<sup>36</sup> The incidence of babesiosis has been increasing in areas of southern New England since the 1990s, and on Block Island, Rhode Island, there may be as many as 900 cases per 100,000 residents per year.<sup>37</sup> There have been more than 40 cases of babesiosis acquired from blood products from asymptotically infected donors,<sup>38</sup> most commonly packed red blood cells but also platelets and frozen-deglycerolized red blood cells,<sup>39</sup> and one case of vertically transmitted infection.<sup>40</sup>

Few cases of babesiosis have been reported outside the United States and Europe. There have been isolated case reports demonstrating active infection (publication of a photomicrograph of a blood smear) in China<sup>41</sup> and South Africa<sup>42</sup> and serosurveys suggesting human babesial infection in Latin America and West Africa. Because of the ubiquity of ticks and the diversity of *Babesia* species and animal hosts, it is likely that transmission to human beings occurs in tropical areas. Some cases of presumed chloroquine-resistant malaria infections may have represented cases of babesiosis because of the difficulty in distinguishing between immature plasmodial and babesial trophozoites in blood smears, and *Babesia* are poorly susceptible to chloroquine.<sup>1</sup>

### Seasonality and Ecology

Human *B. divergens* cases occur mainly in cattle-raising regions during summer months when the presumed vector, *I. ricinus*, is most active and the incidence of red water fever in cattle is greatest.<sup>15</sup> The only known reservoir hosts for *B. divergens* are cattle and reindeer. The American *B. divergens*-like agent (MO-1) is most likely transmitted by *I. dentatus*.<sup>18</sup> Although long thought to be specific for rabbits and birds, this tick appears to feed on humans more frequently than appreciated.<sup>43</sup> Approximately 2% of host-seeking adult *I. dentatus* and 11% to 29% of rabbits were found to be infected during a 5-year study on Nantucket Island. Rabbits were more likely to be actively infected during the fall or spring months, coinciding with the activity of larvae or adults, respectively.<sup>18</sup> Such a pattern is suggestive of maintenance by transovarial transmission, thought to be a main mode of perpetuation for *B. divergens* in the European *I. ricinus*.<sup>15</sup> *Babesia capreoli* (?EU-1) is maintained by *I. ricinus*, probably with roe and red deer as amplifying hosts.<sup>22</sup>

The few reported cases of WA-1 and CA-type babesiosis had their onset between June and August. Vectors and reservoirs remain to be described, although canids, ungulates, and their associated ticks are suspected given the genetic relatedness of these agents to *B. gibsoni* and the mule deer or bighorn sheep babesias, respectively.<sup>6</sup>

In contrast, the ecology of *B. microti* has been well studied.<sup>44</sup> Its enzootic cycle in the northern United States depends on the interaction of subadult deer ticks, *Ixodes dammini* (thought by some to be a variant of *Ixodes scapularis*) and their main source of blood meals, the white-footed mouse (*Peromyscus leucopus*). Deer (*Odocoileus virginianus*) are the hosts on which adult ticks primarily feed, but they are incompetent reservoirs. Adult ticks feed during the autumn and lay eggs during the spring. The eggs hatch in late July, and the emergent larvae feed mainly during August and September, at which time they may acquire babesial infection from an infected mouse. Fed larvae overwinter and molt to the nymphal stage during the spring. The life cycle of the tick is complete when nymphs that have fed on a mouse or other host during the summer molt to the adult stage in the fall.

Humans become infected primarily by the nymphal ticks (Fig. 91-1) rather than adults because survival of *B. microti* during the nymphal to adult tick molt is poor.<sup>45</sup> In addition, people are likely to discover the large adult deer tick and remove it before the tick has fed long enough to deliver an infectious inoculum of sporozoites. Accordingly, in more than

**FIGURE 91-1** Nonfed nymphal deer tick, *Ixodes dammini*. (Cleared and mounted in Berlese's fluid; bar = 595  $\mu$ m.)

80% of reported cases, the onset of illness occurred between May and August, when nymphs are most abundant.<sup>46</sup>

In Taiwan and Japan, the zoonotic vectors of *B. microti* remain to be described, although *Ixodes granulatus* and *Ixodes ovatus* have been found to be infected (personal communications, C. M. Shih, National Defense University, Taipei, 2002; and Masayoshi Tsuji, Rakuno-Gakuen University, Hokkaido, 2003). Various small rodents (*Apodemus* spp. and *Rattus* spp.) are frequently parasitised.<sup>47,48</sup> *Babesia microti* appears to be part of a characteristic microbial assemblage with the agents of Lyme disease, granulocytic ehrlichiosis, and tick-borne encephalitis virus throughout the Holarctic, and therefore knowledge of the life cycle of any one of the assemblage provides basic information about those of the other three.<sup>30,49</sup>

### PATHOGENESIS AND IMMUNITY

Lysis of parasitized erythrocytes leads to anemia, hemoglobinemia, hyperbilirubinemia, and, in severe cases, intense jaundice, massive hemoglobinuria, and renal shut-down. Electron microscopy shows parasite-mediated damage to the erythrocyte membrane with perforations, protrusions, and inclusions.<sup>50,51</sup> There is reduced deformability of infected red blood cells that enhances their removal by the spleen. In experimental *B. bovis* infections, increased peroxidation of membrane lipids appears to be responsible for a further decrease in erythrocyte survival and adherence of infected red blood cells to the endothelium of small blood vessels.<sup>52</sup>

In several of the European cases, autopsy showed parasites in erythrocytes in congested capillaries of various organs, especially the sinusoids of the liver.<sup>53,54</sup> Other findings in these cases and in fatal cases due to *B. microti* suggest a cytokine-mediated shock syndrome. Indeed, laboratory studies of rodents infected by *B. microti* or WA-1 clearly demonstrate overproduction of the proinflammatory mediators tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interferon- $\gamma$ .<sup>55</sup> Mice with a genetic disruption in the TNF- $\alpha$  pathway were less

likely to die of fulminating WA-1 infection, as were CD4 and CD8 gene knockout mice, whereas in  $\gamma\delta$  T-cell knockout mice and control mice WA-1 infection terminated fatally. Thus, CD8+ T cells may contribute to the WA1-induced pathology.<sup>55</sup> In addition, depletion of macrophages and natural killer cells seems to increase susceptibility.<sup>56</sup> Acute tubular necrosis, ischemic necrosis of liver, spleen, pancreas, and heart, non-cardiac pulmonary edema, and swelling and congestion of the brain and other organs have been demonstrated, even in cases in which parasites had been cleared by treatment.<sup>57</sup> Other findings at autopsy have included hemophagocytosis, hypercellularity of the bone marrow, extramedullary hematopoiesis, and hemosiderin deposits in the Kupffer cells and the kidneys, which correspond to findings in histopathologic studies of rodent infections.<sup>58,59</sup>

Asplenia, advanced age, and depressed cellular immunity are associated with severe clinical illness.<sup>60,61</sup> The spleen traps and phagocytoses parasitized erythrocytes, thus limiting parasitemia, particularly early in the infection. Nevertheless, people with intact spleens have died of overwhelming infections, and people without spleens have recovered from babesiosis, even without specific therapy.<sup>61</sup> The severity of illness is greater in people older than 5 years than in younger adults, and overt illness in children seems unusual.<sup>36</sup> As a rule, younger people who become ill are asplenic or immunocompromised or have other underlying medical conditions.<sup>62</sup>

*Babesia microti* infections may be particularly severe in people who are infected with human immunodeficiency virus (HIV) or are receiving corticosteroids or other immunosuppressive therapy.<sup>63</sup> Similarly, hamsters that receive antilymphocyte serum and athymic mice experience high parasitemias and mortality when exposed to *B. microti*.<sup>64,65</sup> CD4 gene knockout mice sustained *B. microti* parasitemias for longer periods of time than did congenic controls.<sup>55</sup> Humoral immunity appears to be less important than cellular immunity in controlling infection. Passive transfer of immune serum to immunodeficient severe combined immunodeficiency (SCID) and nude mice fails to protect them from *B. microti* infection.<sup>66</sup> B cell-deficient mice remain less susceptible to *B. microti* infection, whereas T-cell receptor-deficient mice are readily infected.<sup>67</sup> Antibody titers are generally high when *B. microti* patients present to the clinic, but the magnitude of the titer is not inversely related to parasitemia (S.R.T., unpublished results, 1997). Whether sterilizing immunity develops is questionable; premunition, first described in Theobald Smith's seminal report,<sup>8</sup> may be axiomatic with babesial infections. Human infection may last more than 1 year, even in the absence of underlying illness.<sup>68</sup> Reinfection has not been reported and would be difficult to distinguish from recrudescence of an earlier infection.

## DISEASE

Depending on the species of babesia and host factors, infection can be subclinical, cause a self-limited febrile illness, produce a moderate to severe illness resembling malaria, or progress rapidly to death. Infection with *B. divergens* occurs almost always in splenectomized people and runs a fulminant and usually fatal course without treatment.<sup>15</sup> After an incubation period of 1 to 4 weeks, patients infected with *B. divergens* become acutely ill with high fever, prostration, rigors, diaphoresis,

headache, myalgia, jaundice, and hemoglobinuria. Nausea, vomiting, and diarrhea are prominent, and the liver may be enlarged and painful. Most patients develop acute respiratory distress. Renal failure induced by intravascular hemolysis and hypotension ensues and is followed by coma and death, usually within 1 week of onset of symptoms. The three patients with the U.S. *divergens*-like infection, one of whom died, presented with fever, headache, and rigors; thrombocytopenia, hemoglobinuria, and proteinuria were noted.

Most infections with *B. microti* are subclinical, and available data suggest the same for babesiosis due to WA-1 or CA-1. Subclinical infections have been detected during serosurveys and investigation of blood donors following transfusion-induced cases.<sup>26,27,69</sup> Parasites are not seen in blood smears, but have been isolated by animal inoculation in a small percentage of asymptomatic people with positive serologic tests for antibodies to *Babesia*.<sup>27,36</sup> Subpatent parasitemia in the absence of symptoms may last more than 1 year.<sup>70</sup>

Because of the small number of reported cases, the spectrum of illness among people with clinically apparent WA-1 or CA-type infection remains to be defined. Four of seven people with symptomatic infections had been splenectomized. These included two patients who had severe disease with high parasitemia and multisystem organ failure, one of whom died.<sup>25</sup> The index case—a healthy, spleen-intact man—had a moderately severe illness with a 3% parasitemia, high fever, and a slow recovery.<sup>23</sup> A similar illness occurred in an elderly man with multiple medical problems who acquired infection from a blood transfusion.<sup>26</sup>

People with symptomatic *B. microti* infections typically experience an influenza-like illness 1 to 4 weeks after a tick bite or 4 to 9 weeks following transfusion. There is a gradual onset of malaise, anorexia, and fatigue followed within 1 week by sustained or intermittent fever as high as 40°C, drenching sweats, and myalgia.<sup>69</sup> Nausea, vomiting, headache, shaking chills, dark urine, emotional lability, and depression are not uncommon.<sup>71</sup> Physical examination may show mild splenomegaly and, less often, hepatomegaly. Most patients have mild to moderate anemia; thrombocytopenia; a normal or depressed white blood cell count; mildly elevated hepatic enzymes; and evidence of hemolysis, including hyperbilirubinemia, elevated serum lactic dehydrogenase, and decreased haptoglobin levels. Parasitemias may range from 1% to 20% in spleen-intact people.

After several days to several weeks, fever and more intense symptoms may resolve spontaneously, but weakness, malaise, and fatigue persist for months.<sup>71</sup> In other people, largely the elderly, those without spleens, and those who are immunosuppressed or have other underlying medical problems, illness can be severe, with intense hemolysis leading to jaundice, severe anemia, and renal failure. Parasitemias can reach 85% in asplenic patients.<sup>50</sup> Severe pancytopenia in some cases is due to hemophagocytosis.<sup>72</sup> Disseminated intravascular coagulation, hypotension, and adult respiratory distress syndrome have been seen in fatal cases. Noncardiac pulmonary edema, occasionally requiring mechanical ventilation, may also occur in people with less severe illness several days after beginning therapy.<sup>73</sup> In a series from New York State of 136 patients with babesiosis due to *B. microti*, mortality was 5% despite treatment.<sup>60</sup> Babesiosis in people with acquired immunodeficiency syndrome (AIDS) is characterized by its prolonged duration and frequent relapses. There have been five reports of *B. microti*

infection in people with advanced HIV infection.<sup>63,74–77</sup> Two people who had been splenectomized had parasitemias in excess of 40% and more severe illness than the three who were spleen intact, who had up to 20% parasitemia. Recrudescences occurred in four patients and lasted as long as 400 days after the initial episode; further recurrences were prevented by continual administration of antimicrobial agents.

People with *B. microti* infection who are coinfecting with *Borrelia burgdorferi* experience more symptoms and longer duration of illness than people infected with either organism alone.<sup>78</sup> In a fatal case of a man with coexistent babesiosis and Lyme disease, the cause of death appeared to be related to pancarditis caused by the Lyme disease spirochete.<sup>79</sup> Another man with coinfection developed a more severe case of transverse myelitis than that which is seen with Lyme disease alone.<sup>80</sup> Coinfection with *B. microti* and *Ehrlichia chaffeensis* led to multiorgan failure and death in an 85-year-old man.<sup>81</sup> Antibodies to *Anaplasma phagocytophilum* have been demonstrated in people with babesiosis or antibodies to *B. microti*, but it is not clear that the infections occurred simultaneously.<sup>82</sup> The differential diagnosis for babesiosis includes other tick-borne diseases, including Lyme disease, ehrlichiosis, typhoidal tularemia, and Rocky Mountain spotted fever, all of which may be endemic in the same region, as occurs in New England. *Borrelia burgdorferi* or the agent of human granulocytic ehrlichiosis may be carried simultaneously by a tick carrying *B. microti* and may coinfect a person with babesiosis.<sup>83,84</sup> Other illnesses that may be confused with babesiosis include viral hepatitis, bacterial sepsis, infectious mononucleosis, leptospirosis, malaria, and relapsing fever.

## DIAGNOSIS

The nonspecific symptoms and absence of a history of a tick bite in most cases preclude the ability to make a diagnosis of babesiosis on clinical grounds alone. The definitive diagnosis usually follows demonstration of organisms parasitizing erythrocytes on conventional Giemsa-stained thin films. The small nucleus of *Babesia* can be difficult to identify on thick films, particularly when parasitemia is sparse.

**FIGURE 91-2** *Babesia microti*, hamster. Note multiple rings within single erythrocytes, incomplete closure of rings, and chromatin that extends along the margin of the ring as opposed to being distinctly punctate as in *Plasmodium falciparum*. (Bar = 9.3  $\mu$ m.)

**FIGURE 91-3** *Babesia divergens*, gerbil. Pyriform doublets extending across the diameter of the red blood cell, robust ring forms, and Maltese crosses may be found concurrently. (Bar = 6.7  $\mu$ m.)

Sequential blood smears may be required to detect organisms when the level of parasitemia is low.

*Babesia* is distinguished on blood smear from *Plasmodium falciparum* by a combination of criteria, including the demonstration of basket-shaped and frequently extracellular merozoites (Fig. 91-2), red blood cells containing four or more parasites, and the presence of tetrad forms (Maltese crosses). Tetrad forms, however, are rarely encountered with *B. microti* infection, in contrast to acute *B. divergens* (Fig. 91-3) and WA-1 (Fig. 91-4) infections, in which they are frequent. The absence of hemozoin (malarial pigment) is considered diagnostic for the piroplasms, but early ring stages of the plasmodia also lack pigment. *Babesia divergens* and related infections may be identified by the presence of accolé forms and paired divergent pyriforms occupying no more than 20% to 25% of the erythrocyte area, along with small single oval or round merozoites; high parasitemias are often apparent.

Serologic testing is useful, particularly in diagnosing chronic *B. microti* and WA-1 infections in which the parasitemia is subpatent. The indirect fluorescent antibody test

**FIGURE 91-4** *Babesia gibsoni* (WA-1), hamster. Rings are smaller and more delicate than in *Babesia microti*; Maltese cross forms are commonly observed. (Bar = 7.5  $\mu$ m.)

using antigen derived from infected hamster red blood cells<sup>85</sup> is sensitive and specific, and it is the serologic method of choice. Indeed, in cases in which parasitemia is difficult to detect, detection of specific immunoglobulin M (IgM) confirms a clinical diagnosis of babesiosis.<sup>86</sup> Absence or low titers of specific antibodies against *B. microti* when blood smears contain parasites suggests an infection by another *Babesia* sp. or an immunocompromised patient (splenectomy, HIV, or recent infusion of anti-B-cell antibody). Because specific antibodies do not become detectable until at least 1 week after onset of illness, serology is not reliable for diagnosis of the rapidly fulminating *B. divergens* babesiosis.<sup>15</sup>

Subinoculation of a sample of blood into hamsters facilitates diagnosis of *B. microti* infection when smears are negative. Approximately 300 parasites are sufficient to induce persistent parasitemia, which becomes detectable between 1 and 6 weeks following inoculation. *Babesia divergens* can be isolated by inoculation of gerbils, but this procedure is only useful for confirming the diagnosis of this rapidly progressive infection in retrospect. Polymerase chain reaction (PCR)-based assays, which can detect *Babesia* DNA corresponding to three parasites in a 100- $\mu$ L sample of blood, have the advantage of yielding a diagnosis in less than 1 day.<sup>87</sup> In addition, sequencing of the amplification products may provide more rapid specific identification than immunological analysis or animal inoculation studies when the identity of the infecting parasite is questioned.

## TREATMENT AND PROGNOSIS

The combination of quinine (650 mg orally three times daily and clindamycin either 1.2 g intravenously twice daily or 600 mg orally three times a day) can be used to treat babesiosis due to all species.<sup>88,89</sup> The pediatric doses are quinine 25 mg/kg/day and clindamycin 20 to 40 mg/kg/day, both in three divided doses.<sup>88</sup> Treatment should be continued for at least 7 days or until parasitemia remits. Although an in vitro analysis of drug efficacy against *B. divergens* suggested that quinine has poor antibabesial activity<sup>90</sup> and therefore clindamycin alone (which demonstrated significantly greater activity) may be used to treat cases of *divergens* babesiosis,<sup>91</sup> without experimental trials in animals confirming this assertion such a course of action cannot be recommended. In particularly severe cases of *B. divergens* babesiosis, complete blood exchange transfusion (two or three blood volumes) should be undertaken, followed by treatment with clindamycin and quinine.<sup>92</sup> Because *B. divergens* parasitemias increase very rapidly, any case of babesiosis acquired in Europe should be regarded as an emergency requiring prompt treatment and frequent monitoring of blood smears.

Babesiosis due to WA-1 appears to respond to the combination of quinine and clindamycin, but the small number of cases that have been treated to date does not permit strong conclusions about the efficacy of this regimen. Because illness due to *B. microti* is often mild and short-lived, not all cases require treatment. For people with *B. microti* infections that are non-life-threatening, the combination of atovaquone and azithromycin may be used. A prospective randomized trial demonstrated that patients treated with atovaquone (750 mg orally every 12 hours for 7 days) and azithromycin (500 mg orally on day 1, then 250 to 600 mg/day for 7 days) cleared

parasitemia as effectively as did those receiving clindamycin and quinine, with fewer side effects.<sup>93</sup> Atovaquone is extremely active against both *B. microti* and *B. divergens* in rodents, but recrudescences of parasitemia occur.<sup>94,95</sup> Azithromycin is active against *B. microti* as well,<sup>96</sup> and it prevents recrudescences in animals when given along with atovaquone.<sup>94</sup> Combination therapy including atovaquone or azithromycin or both and also quinine or clindamycin has been used as an alternative for treating human babesiosis when other regimens have failed or patients have developed side effects while receiving standard therapy.<sup>93,94</sup> Quinine and clindamycin should be given if the symptoms are sufficiently severe or if the patient is elderly, splenectomized, or immunocompromised. Treatment may occasionally fail, especially in high-risk patients or in those who must discontinue quinine due to side effects such as severe tinnitus. In most patients who complete the full regimen, parasite DNA seems to become undetectable by PCR within 1 month.<sup>68</sup> In a minority of cases, particularly in immunocompromised patients, symptoms may resolve but parasitemia persists.<sup>63,97</sup> Exchange transfusion should be considered in severely ill patients with parasitemias in excess of 10% and evidence of severe hemolysis or organ failure.<sup>98</sup> Following treatment, patients with AIDS should remain on suppressive therapy to prevent relapses.<sup>63</sup> The ideal regimen and duration of suppression have not been determined, but combinations of quinine, clindamycin, and other drugs have been used for periods of 6 months or maintained for life.

A variety of other agents have been tried for treating infected humans and experimental animals. Administration of chloroquine, sulfadiazine, or pyrimethamine failed to reduce *B. microti* parasitemia in hamsters,<sup>87</sup> and chloroquine and cotrimoxazole did not eliminate parasites from people infected with this organism, although symptomatic improvement was seen among people who received chloroquine.<sup>99</sup> Pentamidine and diminazene are active in animal models, but results of treatment of infected humans with pentamidine have been mixed,<sup>100</sup> and a patient successfully treated with diminazene developed complications resembling Guillain-Barré syndrome.<sup>101</sup> High doses of tetracyclines are active against *B. microti* in rodents, and doxycycline in combination with other agents appears to have efficacy in refractory cases in people with AIDS.<sup>63</sup> However, patients who are treated with a tetracycline for Lyme disease (e.g., 100 mg doxycycline orally twice a day for 14 days) appear to require specific antibabesial treatment if they are coinfecting (T. J. Lepore, Nantucket Cottage Hospital, Nantucket, MA, personal communication, 1997). *Babesia microti* infections in hamsters were successfully cleared by two experimental 8-aminoquinolines (WR006026 and WR238605) under evaluation as antimalarials, and it may be that these compounds will eventually provide another treatment option. Other recently developed antimalarials (mefloquine, halofantrine, and artemisinin), however, were not effective.<sup>102</sup>

## PREVENTION AND CONTROL

Repellents or arthropod toxicants are useful for personal protection. Permethrin-based formulations applied to shoes, socks, and trousers are particularly active against ticks,<sup>103</sup> although ticks may attach and feed briefly before succumbing to permethrin intoxication. Commonly used DEET (diethyltoluamide) repellents will also repel most ticks but are more

volatile and require frequent reapplication. Preventing ticks from crawling underneath clothing by simply tucking trouser cuffs into socks also greatly reduces the risk. Also, because delivery of an infectious inoculum usually requires more than 1 day of tick attachment, the body surface of people who have visited a site where transmission is intense should be examined daily and all ticks should be removed promptly with forceps.

Various public health strategies may be followed to protect human populations against zoonotic babesial infection. The abundance of vector ticks may be temporarily reduced by spraying acaricides. Less environmentally intrusive applications of fiber-formulated permethrin<sup>104</sup> interrupt transmission of *B. microti* infection when rodents carry fibers into their nests and acaricide accumulates on the coats of the rodents and in sites where ticks rest. Acaricides may be applied to presumed cattle reservoirs for *B. divergens* to reduce the prevalence of infectious ticks. In areas of *B. microti* transmission, reducing the density of deer that serve as hosts to adult ticks may greatly diminish the local populations of deer ticks.<sup>105</sup> Reducing the density of rodent reservoirs seems impractical.

Efforts to develop veterinary vaccines against babesiosis have had mixed success. Cattle have been successfully vaccinated with attenuated parasites or exoantigen preparations, but recombinant antigens seem less effective due to parasite strain polymorphism. In addition, the mechanisms of protective antibabesial immunity are incompletely described.<sup>106</sup> Crude parasite lysates have been successfully used to immunize hamsters against infection by *B. microti*,<sup>107</sup> but subunit immunogens have yet to be described. Two immunodominant antigens, of 37 and 58 kDa, show promise as the basis for a subunit vaccine inducing protective immunity to *B. divergens*.<sup>108</sup> Vaccination as a strategy for preventing babesiosis in humans therefore seems premature but not without promise. People who are at risk of developing severe infections should carefully practice personal protection measures.

# African Trypanosomiasis (Sleeping Sickness)

JACQUES PÉPIN  
JOHN E. DONELSON

## INTRODUCTION

Human African trypanosomiasis (HAT), or sleeping sickness, is a purely African disease caused by two morphologically identical subspecies of trypanosomes—*Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*—transmitted to humans by tsetse flies. Clinically, *T. b. gambiense* HAT is characterized by an early stage during which trypanosomes are found in the blood or lymph node aspirates of mostly asymptomatic persons and by a late stage during which there is involvement of the central nervous system (CNS) with somnolence, other neurologic symptoms, and trypanosomes in the cerebrospinal fluid (CSF). *T. b. rhodesiense* HAT, which is sometimes seen in short-term visitors to eastern and southern Africa, is a much more acute febrile illness occurring within days of the infective bite and which, if untreated, can be fatal in a matter of weeks.

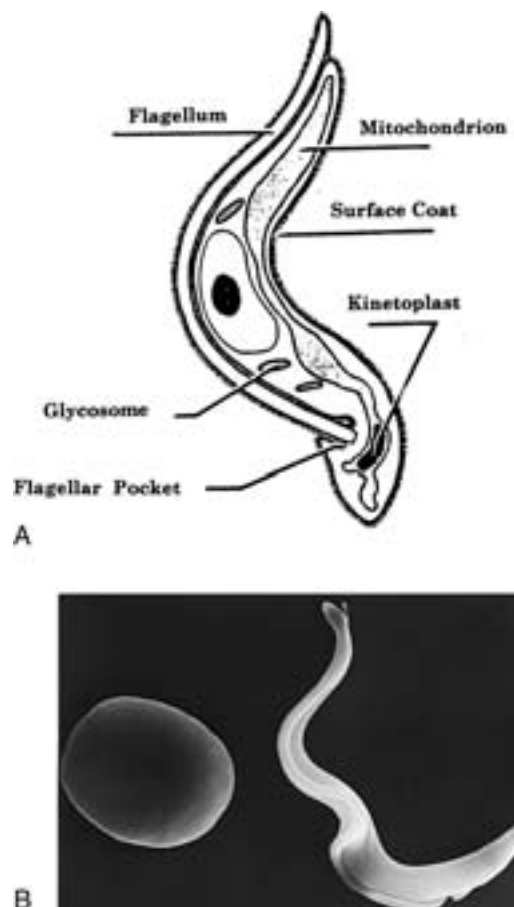

## AGENT

*T. b. gambiense* and *T. b. rhodesiense* are morphologically identical to a third salivarian trypanosome, *Trypanosoma brucei brucei*, which infects domestic and wild animals but does not survive in humans because it is lysed by apolipoprotein L-I in the high-density lipoprotein (HDL) fraction of human serum.<sup>1,2</sup> This group of three subspecies is often referred to as the *T. brucei* complex. Several other African trypanosome species are important pathogens of domestic livestock and wildlife in Africa but do not infect humans and are not discussed here.

The genus *Trypanosoma* occurs within the order Kinetoplastida. The single large mitochondrion of these organisms contains an appendage called the kinetoplast that lies in close proximity to the basal body at the base of the flagellum (Fig. 92-1). In the *T. brucei* complex, the kinetoplast contains as much as 10% of the total DNA of the organism. This DNA is organized into homogeneous maxicircle DNA molecules (about 20,000 base pairs each), which are equivalent to mitochondrial DNAs of other organisms, and heterogeneous minicircle DNA molecules (about 1000 base pairs each). A unique feature of organisms in the order Kinetoplastida is

that some of their kinetoplast DNA genes are transcribed into RNAs that must be extensively edited by insertions or deletions of uridine nucleotides at many locations along the messenger RNA (mRNA) molecule before the correct mitochondrial proteins can be synthesized.<sup>3</sup> In the *T. brucei* complex, as many as 50% of nucleotides in some kinetoplast mRNAs are added or deleted after the initial synthesis of the RNA molecule. The reasons for the existence of this kinetoplast RNA editing and, indeed, the need for the kinetoplast itself are unknown, but this distinctive property of trypanosomes and related organisms does offer an attractive target for future drug development. The sequence determination of the  $3.5 \times 10^7$  base-pair DNA genome in the nucleus of *T. b. brucei* is nearing completion<sup>4,5</sup> and may provide the foundation for identification of potential new drug targets.

During their life cycle the members of the *T. brucei* complex cycle between the mammalian bloodstream and several species of tsetse flies of the genus *Glossina*. When a tsetse fly bites an infected person, or an animal in the case of *T. b. rhodesiense*, trypanosomes in the bloodstream can be ingested with the blood meal (see Fig. 92-1). In the fly, the infected blood moves to the lumen of the midgut, where the bloodstream trypanosomes transform during a 2- to 3-day period into the

**FIGURE 92-1** A, Schematic diagram of a bloodstream trypanosome showing some of its subcellular organelles and the surface location of the variant surface glycoprotein. B, Scanning electron micrograph of a bloodstream *Trypanosoma brucei rhodesiense* adjacent to a rat red blood cell. (×5500.)

procyclic stage. This transformation is accompanied by many developmental changes including an increase in body length, a switch from anaerobic to aerobic metabolism, and a change in the main nutritional carbon source from glucose to proline, which is also used as the predominant energy source by the tsetse fly itself during flight.<sup>6,7</sup> In addition, the major protein on the surface of bloodstream trypanosomes, the variant surface glycoprotein (VSG), is replaced by an invariant surface protein called procyclin. After 2 to 3 weeks of multiplication in the midgut, the procyclic trypanosomes migrate to the salivary gland, where they undergo several additional developmental changes, culminating in the formation of the mature metacyclic stage. Metacyclic trypanosomes reacquire a VSG

coat and stop multiplying. An infected tsetse fly can harbor as many as 10,000 to 20,000 metacyclic trypanosomes, of which one is potentially sufficient to initiate the mammalian infection if transmitted during the fly bite. Each trypanosome of the mature metacyclic population is completely covered with about  $10^7$  copies of a single VSG, but the population as a whole expresses 10 to 20 different metacyclic VSGs.<sup>8</sup> Moreover, one study showed that these metacyclic VSGs gradually diverged over a 20-year period,<sup>9</sup> indicating that a vaccine directed against the metacyclic VSGs would not be successful.

The tsetse fly injects the metacyclic trypanosomes into the connective tissue of the skin, where a temporary local inflammation, called a chancre, often develops. From this initial

## African Sleeping Sickness

### *Trypanosoma brucei gambiense/rhodesiense*

portal of entry, the parasites enter the draining lymphatics and pass into the bloodstream through the thoracic duct. They begin to multiply again by binary fission and transform back into the bloodstream form, returning to anaerobic glycolysis as the main source of adenosine triphosphate (ATP). They continue, however, to express the metacyclic VSGs on their surface for about 5 days after the initiation of infection. They then switch from the expression of metacyclic VSGs to the bloodstream VSGs, one of which is sometimes the same VSG as on the surface of trypanosomes ingested by the fly.<sup>10</sup> The slender bloodstream form of the parasite actively divides every 5 to 10 hours, whereas the shorter, stumpy form does not divide but has a more developed mitochondrion and is thought to be more infective to the insect. These bloodstream forms can traverse the walls of the blood and lymph capillaries to the connective tissues and eventually enter the CSF and the brain. The parasite's life cycle is completed when a tsetse fly takes up the bloodstream forms while feeding on an infected mammal.

While in the bloodstream, African trypanosomes are in constant contact with their host's immune system. As a result, they have evolved sophisticated mechanisms with which to evade immune attack. The VSG is a crucial component of one of these evasion mechanisms, a phenomenon called antigenic variation. As early as 1910, HAT was reported to be characterized by successive waves of parasites in the blood.<sup>11</sup> It is now well known that these peaks of parasitemia are due to trypanosomes expressing antigenically different VSGs.<sup>12</sup> The nuclear DNA of the *T. brucei* complex contains as many as 1000 different VSG genes. Usually each trypanosome expresses one, and only one, of these VSGs at a given instant. The 10<sup>7</sup> copies of a VSG on a trypanosome represent about 5% of the total protein of the organism. The major function of all this protein on the surface of the living trypanosome is to serve as a barrier to protect other invariant constituents of the organism's outer membrane from attack by the immune system.

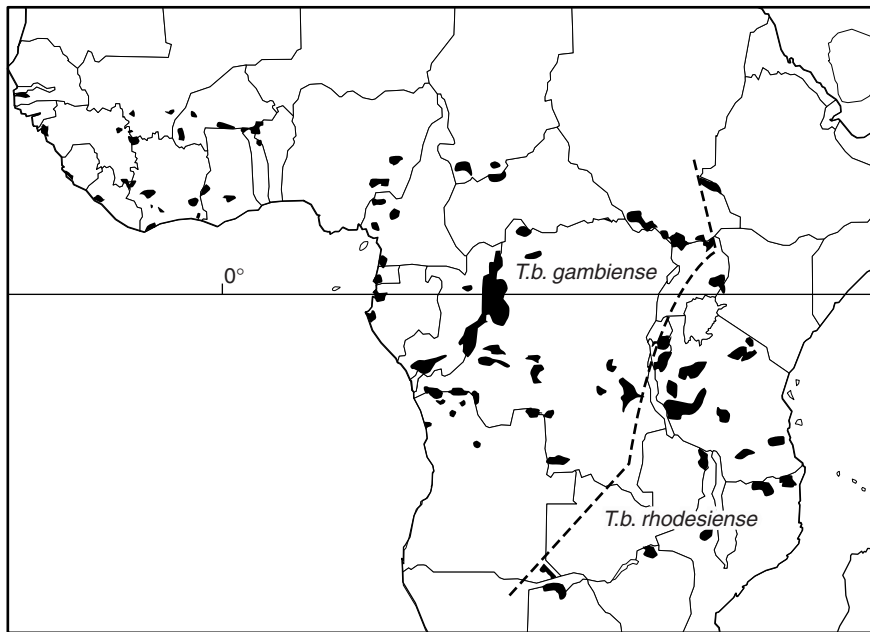

The three-dimensional structures of two different VSGs have been shown by x-ray crystallography to be cylindrical, allowing them to pack very closely together on the parasite's surface. During an infection, antibodies are continually raised against the VSG, but the trypanosome population manages to escape total destruction because individual parasites occasionally undergo antigenic variation by switching spontaneously from the expression of one VSG to another. New antibodies must be directed against the VSG of the switched parasite and its descendants, enabling the population as a whole to stay one step ahead of this humoral (B-cell) immune response. The switch rate of the bloodstream trypanosome's antigenic variation appears to range between 10<sup>-2</sup> and 10<sup>-6</sup> per parasite per doubling time.<sup>13</sup> The switch itself is often associated with spontaneous VSG gene rearrangements that maneuver duplicated copies of silent VSG genes into special gene expression sites located near the ends of some chromosomes, where they are transcribed into mRNA. Sometimes these rearrangements result in the formation of new VSG genes that are mosaic or mutated versions of preexisting genes.<sup>14,15</sup> This ability to create new VSG gene versions during the DNA rearrangements likely means that bloodstream trypanosomes have the potential to express sequentially a much larger repertoire of VSG proteins than they have VSG genes. Hence, the development of a HAT vaccine directed against bloodstream VSGs is also unlikely.

The tsetse fly vector corresponds to the *Glossina* genus, found only in Africa, which contains 22 species, only a few of them being involved in the transmission of HAT: the riverine *palpalis* group (*G. palpalis*, *G. tachinoides*, and *G. fuscipes*) for *T. b. gambiense*, and the *morsitans* group (*G. morsitans*, *G. pallidipes*, and *G. swynnertoni*) for *T. b. rhodesiense*. Tsetse flies live in hot, humid, and dark ecologic niches, and their distinct requirements relate to epidemiologic differences between *gambiense* and *rhodesiense* HAT. The *palpalis* group is found mostly in forests lying on the banks of a river and humans are a variable source (10% to 40%) of their blood meals, while the more zoophilic *morsitans* group is seen in the woodland and thickets of East African savannas. Once infected with trypanosomes, tsetse flies remain infected for the rest of their lives (a few months). Less than 5% are infected in epidemic areas.

## EPIDEMIOLOGY

HAT is endemic only in sub-Saharan Africa between latitudes 15 degrees north and 15 degrees south, corresponding to the distribution of its vector.<sup>16,17</sup> Its incidence increased considerably at the beginning of the 20th century as a consequence of population migrations brought on by colonization, when huge epidemics devastated several regions of Africa. There is some debate, however, whether this might have been initially exaggerated to cover up a genocide in the Free State of Congo.<sup>18</sup> Reports of control programs in the 1920s and 1930s described tens of thousands of cases detected each year in many countries. In some endemic areas HAT caused almost half of the overall mortality. Trypanosomiasis control was organized in West and Central Africa around mobile case-finding teams that regularly examined the population of endemic foci through cervical lymph node palpation and aspiration to detect and then treat infected but asymptomatic persons. In the late 1940s and 1950s, millions of people were given pentamidine "chemoprophylaxis" twice a year, but it probably corresponded more to early treatment than to prevention. Such initiatives were highly successful, and the incidence of HAT decreased dramatically. After the end of the colonial era, HAT remained at a low level ("residual endemicity") or disappeared in countries able to maintain some case-finding activities, but it increased considerably when such programs were interrupted for just a few years. As a result, the distribution of sleeping sickness today parallels that of wars or civil conflicts that have recently devastated parts of Africa, with the highest incidences occurring in the Democratic Republic of Congo (DRC), Angola, and Sudan. Underdiagnosis and underreporting are substantial. The total number of cases was recently estimated to be around 100,000 per year, with probably between one third and one half of cases remaining undetected and untreated.<sup>16</sup> The burden of HAT was estimated in a 2003 WHO Report to be 48,000 deaths per year and 1.5 million disability-adjusted life-years lost.<sup>19</sup>

Gambian HAT is endemic in western and central Africa and Rhodesian HAT in eastern and southern Africa. Uganda is the only country in which both subspecies are known to present. In West Africa, the disease has disappeared from Senegal, The Gambia, Guinea-Bissau, Sierra Leone, and Ghana for ecologic reasons that are poorly understood, since significant tsetse fly populations remain. A few hundred cases are diagnosed each year in Côte d'Ivoire, Guinea, and Nigeria. The country with

Redrawn from World Health Organization: Control and surveillance of African trypanosomiasis. Report of a WHO expert committee. World Health Organization Technical Report Series no. 881, 1998.

by far the highest incidence is DRC, where 15,000 to 25,000 cases are reported each year. Given the breakdown of its health system, the lack of resources for mobile teams, and the dismal road conditions, the true incidence in DRC could be at least twice that high, with thousands of patients dying untreated in remote villages.<sup>20</sup> The epidemic has also reached Kinshasa, where almost 1000 cases were diagnosed in 1999.<sup>21</sup> In Angola, about 5,000 cases of Gambian HAT are reported annually. There is also significant endemicity in Congo-Brazzaville and Central African Republic (around 1000 cases per year) and residual endemicity in Gabon, Cameroon, and Equatorial Guinea. There is a major, ongoing *T. b. gambiense* epidemic in southern Sudan where war has made control and surveillance very difficult. In East Africa, an epidemic of Rhodesian HAT in the historical Busoga focus of southeastern Uganda has been reduced from 8465 cases in 1981 to 271 cases in 1998 by tsetse fly trapping and case finding. Gambian HAT persists, however, in the northwestern region of the country. Only residual Rhodesian HAT endemicity occurs elsewhere in eastern and southern Africa, with fewer than 200 reported cases per year in Tanzania, Zambia, Kenya, Malawi, and Mozambique. Each year, approximately 30 cases of *T. b. rhodesiense* HAT are diagnosed in non-African tourists, especially visitors to the Serengeti,<sup>22</sup> while about 20 cases of *T. b. gambiense* HAT are diagnosed in Africans who have migrated outside the endemic areas.<sup>23</sup>

The major determinants of the epidemiology of *T. b. gambiense* HAT are (1) the long duration (up to several years) of infection in human hosts, with cycles of intermittent parasitemia; (2) human-fly contact and infection rates among tsetse flies; and (3) the efficacy of passive and active case finding.<sup>16</sup> Human-fly contact can be enhanced by changes in tsetse fly density, distribution, and feeding habits or in human behavior that results in people spending more time in areas of high

fly density. Breakdowns in active case finding and, to a lesser extent, in passive detection by multipurpose health facilities allow the human reservoir to expand and increase the percentage of infectious tsetse flies. Significant immunity appears after an adequately treated first episode of Gambian HAT,<sup>24</sup> which might explain the resurgence of HAT in exactly the same foci as 50 years earlier: After years of high incidence and successful treatment of most cases, a large proportion of the population becomes immune and decades are necessary before the pool of immunologically naive persons is large enough to sustain an epidemic. Familial clustering of cases was also observed, the risk of HAT in a child being higher if the mother (but not the father) had had HAT before. This finding was thought to reflect shared exposure or congenital infections rather than a genetically determined susceptibility.<sup>25</sup> There seems to be little or no interaction between HAT and human immunodeficiency virus (HIV) infection.<sup>26</sup> Mainly because of the long incubation period, there is no seasonal variation in Gambian HAT incidence.

Domestic animals (pigs, goats, dogs, sheep, cattle, and even chickens) can be infected with *T. b. gambiense*. The importance of these animal reservoirs is probably marginal in high-incidence countries of Central Africa, but they might play a role in the persistence of the disease in countries of West Africa, where the size of the human reservoir has been reduced through control efforts.<sup>16</sup> In contrast, *T. b. rhodesiense* HAT is a zoonosis and to some extent an occupational disease, with many species of game animals and cattle harboring the parasite and sustaining sporadic transmission to humans.<sup>16</sup> Person-to-person spread has been implicated in the recent epidemic of Rhodesian HAT in Uganda, but by and large this subspecies offers less potential for large-scale epidemics because of its acute nature. Changes in agricultural practices and movements of cattle have been incriminated as favoring the spread of the parasite.<sup>27</sup>

## DISEASE

In Gambian HAT, the asymptomatic phase can last many months, if not years. Intermittent fever then appears with nonspecific symptoms such as headache, myalgia, and malaise. These symptoms last a few days before subsiding and reappearing weeks later, and correspond to successive waves of antibodies produced in response to antigenic variation of the VSGs. Eventually weight loss and asthenia become significant, and pruritus can be troublesome. Transient edema, mostly of the face, is seen in fewer than 10% of patients. After months of nonspecific symptoms, evidence of CNS involvement makes the diagnosis obvious. Somnolence is seen in 80% of late-stage patients, and only the occasional patient experiences both diurnal somnolence and nocturnal insomnia. Most patients then complain of constant and severe headaches that are unresponsive to analgesics. Behavior change or psychosis is seen in 5% to 10% of cases. If untreated, the somnolence progresses to stupor and coma, and the ultimate cause of death is often a bacterial superinfection such as aspiration pneumonia. Convulsions are rare in adults but more common in children (up to 30%), among whom retardation in psychomotor development, language, or walking, and irritability can be the presenting symptoms. In children, lymphadenopathy is less prominent and the disease progresses more rapidly to overt CNS involvement than in adults. Various endocrine disorders have been reported: hypogonadism, amenorrhea, infertility, and low triiodothyronine ( $T_3$ ) or low thyroxine ( $T_4$ ) syndromes but rarely frank hypothyroidism. There are some exceptional cases of healthy carriers who remained parasitemic and asymptomatic for years without treatment, but untreated HAT is ultimately fatal to almost all infected persons.

An inoculation chancre is rarely recognized in persons repeatedly bitten all year long by various insects but is more frequent in the rare Europeans who acquire Gambian HAT.<sup>23,28</sup> Fewer than half of asymptomatic patients actively detected during surveys, but up to 85% of those passively detected in a hospital, have the classic Winterbottom cervical lymphadenopathies, which are soft, painless, 1 to 2 cm in diameter, numerous, and rather mobile. Lymphadenopathy can be less typical, and in persons from high-incidence areas, any lymph node large enough to be aspirated should be aspirated. As the disease progresses, lymphadenopathy becomes less obvious. Cutaneous lesions, the trypanids, are seen only in whites. A modest splenomegaly can be found (10% to 20%); hepatomegaly is rare (1%). On neurologic examination, patients do not have neck stiffness apart from the occasional patient with a very high CSF white blood cell count (WBC). Focal signs (hemiparesis, hemiplegia) are unusual, but in a patient from a high-incidence community, any neurologic sign should be considered as potentially caused by HAT until proved otherwise. The hand-chin reflex can be elicited in half the patients. Tremors are not unusual; choreoathetosis is seen mostly in patients with multiple relapses. Despite *in vitro* evidence of immunosuppression, infections seen in HAT patients relate to the altered level of consciousness rather than to opportunistic pathogens.

In Rhodesian HAT, the clinical presentation is similar but much more acute. Most patients have been sick for less than a month when the diagnosis is made.<sup>29</sup> Inoculation chancres are more common than in Gambian HAT, and trypanosomes

can sometimes be seen microscopically in fluid expressed from them. Lymphadenopathy is less frequent than in Gambian HAT and is often submandibular, axillary, or inguinal rather than cervical.<sup>29</sup> Myocarditis is an uncommon complication. In tourists from nonendemic countries, the inoculation chancre is often present when the patient develops an acute disease that, if untreated, can rapidly progress to multiorgan involvement and disseminated intravascular coagulation.<sup>30</sup>

## PATHOGENESIS AND IMMUNITY

The immune response and pathogenesis that develop during HAT are complex and poorly understood. From an immunologic perspective, a trypanosome may be regarded as a package of thousands of nonvariable antigens surrounded by 10 million copies of a variable antigen, the VSG.<sup>6</sup> Since bloodstream trypanosomes are destroyed during an infection, the immune system is continually exposed to massive amounts of invariant antigens and VSGs, but the immune responses to these foreign antigens are not protective because the invariant antigens inside the living trypanosome are inaccessible and the readily accessible VSGs periodically switch via antigenic variation. Hence, many of the immune events observed in HAT are likely the result of the perpetual presence of ever-changing VSGs mixed with many other invariant antigens, a scenario that mimics successive infections by related but unidentical organisms.

In experimental laboratory animals, the immune responses to a trypanosome infection are dominated by two overwhelming phenomena: massive nonspecific polyclonal activation of B cells and generalized suppression of some humoral (B-cell) and cellular (T-cell) immune functions. The polyclonal B-cell activation results in a large production of immunoglobulin M (IgM), the first class of antibody to be generated by the appearance of new foreign antigens. This activation is not triggered entirely by the continually changing epitopes of the different VSGs, however, since the newly synthesized antibodies do not react solely with VSGs and other trypanosome antigens. They frequently are heterospecific in their reactivity and can be autoantibodies directed against the proteins and nucleic acids of the host. It has been proposed that an unknown non-VSG molecule of trypanosomes,<sup>31,32</sup> or perhaps even the VSG itself,<sup>33</sup> serves as a mitogen, causing this massive nonspecific expansion of B cells and the subsequent increase in immunoglobulin concentration. The greatly elevated levels of IgM and resultant antigen-antibody complexes in turn cause hyperplasia of the reticuloendothelial system, especially the spleen and lymph nodes, and are likely responsible for many of the pathogenic characteristics of the disease.

The other striking immune feature of HAT is suppression of immune responses other than the initial B-cell activation, which affects a large variety of both B-cell and T-cell functions and seems to inhibit many secondary immune events (reviewed by Sileghem and colleagues<sup>32</sup>). For example, the enormous IgM production is not followed by the normally concomitant increase in IgG and the other antibody classes, and T-cell proliferation is severely suppressed. However, the concentration of the cytokine interferon-gamma ( $INF-\gamma$ ) is greatly increased in experimental animals infected with *T. brucei*. Macrophage activity is enhanced during trypanosome infection, perhaps by the increase in  $INF-\gamma$ , and the elimination of trypanosomes

by antibodies is thought to be mediated by opsonization and destruction by liver macrophages, rather than by complement-mediated lysis.<sup>34</sup> Levels of some cytokines such as interleukin-2 (IL-2) decrease during trypanosome infections, and this may contribute to the lack of T-cell proliferation. Although the coexistence of massive polyclonal B-cell expansion and significant immunosuppression appears at first glance to be counterproductive, both phenomena obviously generate an environment conducive to perpetuation of the infection. Clearly, our understanding of the myriad of immune events occurring during HAT could benefit from more laboratory-based research.

HAT is often accompanied by anemia, which may be caused by hemolysis induced by the elevated immune complexes, although other mechanisms are involved (reviewed by Poltera<sup>35</sup>). Platelet destruction and increased vascular permeability occur, and the parasites readily infiltrate the interstitial spaces and lymphatic system, where they continue to multiply. There is widespread lymphadenopathy due to the increased lymphocytic proliferation, which can be followed by fibrosis. The spleen is sometimes enlarged, with generalized cellular proliferation, congestion, and focal necrosis. The spleen and lymph nodes can both develop endarteritis with perivascular infiltration by trypanosomes and lymphocytes. The heart can also be affected, particularly in Rhodesian HAT, in which a pancarditis can develop that involves all cardiac structures, including valves and the conduction system, resulting in cardiac failure and electrocardiographic changes.<sup>36</sup>

The late stage of HAT is defined by the detection of trypanosomes in the CSF via lumbar puncture (LP) or CSF pleocytosis (which appears earlier in CSF obtained by cisternal puncture than by LP). The pressure and total protein content of the CSF are increased, and there is infiltration by immune complexes, white blood cells, and sometimes small numbers of eosinophils and morular (Mott) cells, which are thought to be IgM-containing plasma cells that fail to secrete their antibodies. In the brain, the parasites are found mainly in the frontal lobes, the pons, and the medulla, where they are associated with diffuse meningoencephalitis, parenchymal edema, and dura-arachnoid adhesions. Lymphoid cells often infiltrate the brain through the space surrounding the blood vessels, and hemorrhages can occur. Widespread multifocal white matter degeneration develops, especially during the final stages of the disease, but there are no structural nerve cell alterations.<sup>37</sup> The actual cause of the cerebral damage in late-stage HAT remains uncertain but the lesions may be mediated by immunologic reactions that occur around the blood vessels and affect the brain parenchyma.

## DIAGNOSIS

Anemia, thrombocytopenia, an increased erythrocyte sedimentation rate, hypergammaglobulinemia, and hypoalbuminemia are frequent but nonspecific. Eosinophilia is not seen, but an elevated serum IgM level (up to 16 times the normal concentration) is suggestive of HAT. The diagnosis requires, however, the detection of trypanosomes. Examination of lymph node aspirates is the classic detection method in Gambian HAT: A 25-gauge needle is inserted in the node, which is massaged for 1 minute while the needle is rotated, the needle is withdrawn and with a syringe the lymph node "juice" is pushed

out on a slide, which must be examined immediately at  $\times 400$ . Trypanosomes can be seen moving for 15 to 20 minutes afterward and are more numerous on the edges of the coverslip. In the absence of lymphadenopathy or if the aspirate is negative, the diagnosis can be made on a wet smear of blood (a drop of unstained blood between slide and coverslip) or on a Giemsa-stained thick smear. The latter is more sensitive because of the larger quantity of blood, but a microscopist who must examine 50 smears per day usually prefers the wet smear approach in which trypanosomes can be readily detected by their high mobility. Because of the low level of parasitemia and its fluctuation over time, repeated examinations on consecutive days may be necessary before a trypanosome is seen. Patients in whom HAT is suspected but for whom those assays are negative should be tested with other techniques. The most sensitive is the mAECT (miniature anion-exchange centrifugation technique). Blood is filtered through an anion-exchange resin that retains blood cells but not trypanosomes. The eluate is then centrifuged, followed by a direct microscopic examination of the pipette in a viewing chamber.<sup>38</sup> The hematocrit centrifugation technique for an examination of the buffy coat is an alternative. The lower limits to the number of parasites detectable by the different methods are  $10^4/\text{mL}$  for the wet smear,  $5 \times 10^3/\text{mL}$  for the thick smear,  $5 \times 10^2/\text{mL}$  for the hematocrit centrifugation, and  $10^2/\text{mL}$  for the mAECT. The quantitative buffy coat technique using acridine orange stain is also quite sensitive.<sup>39</sup> The kit for *in vitro* isolation and detection of trypanosomes and the polymerase chain reaction remain research tools unlikely to be used in the field in the near future.<sup>40,41</sup>

As the disease progresses, it becomes more difficult to find parasites in the blood and lymph nodes, and more likely that only the CSF will reveal trypanosomes. An LP should be performed on all patients for whom parasites have been documented in any of the preceding tests, and on patients with symptoms of sleeping sickness but negative assays. The most sensitive techniques for detecting CSF trypanosomes are the double centrifugation (6 to 8 mL of CSF is obtained and, after a first centrifugation, the sediment is drawn into a capillary tube, centrifuged again, and examined immediately<sup>42</sup>) or simple centrifugation in a sealed Pasteur pipette.<sup>43</sup> The CSF WBC is measured with a counting chamber; patients with a WBC higher than  $5/\text{mm}^3$  are arbitrarily considered to be in late stage. Many patients without neurologic symptoms will have a slightly elevated CSF WBC; those with overt somnolence usually have a WBC between 100 and  $500/\text{mm}^3$ . The CSF is clear, and its white blood cells are essentially mononuclear. Measuring CSF proteins adds little new information because they are usually elevated (0.4 to 1.0 g/L) along with the WBC. Large eosinophilic plasma cells (Mott cells) are "typical" of HAT but rarely seen. In endemic areas, clinicians sometimes treat patients with a presumptive diagnosis: No trypanosomes have been found but the typical symptoms, residence in a known focus, positive serologic reactions, and elevated CSF WBC make the diagnosis virtually certain.

Many serologic techniques have been developed for Gambian HAT to improve the efficacy of case-finding surveys by identifying serologically positive persons on whom parasitologic assays are selectively performed. Because of drug toxicity, treatment is generally given only to patients in whom trypanosomes are subsequently documented. The only

field-adapted assay, the CATT (card agglutination test for trypanosomes, Institute of Tropical Medicine, Unit of Applied Technology and Production, Nationalestraat 155, B-2000 Antwerpen, Belgium), can be performed without electricity, and its results are available within 10 minutes. It has excellent (98%) sensitivity but its specificity (95%) is less satisfactory owing to cross-reactivity with animal trypanosomes.<sup>44</sup> Depending on the prevalence of Gambian HAT in the population to be tested, its positive predictive value is 66% to 89% in passive case-finding in a hospital but only 20% to 30% in active case-finding surveys. Using the CATT on diluted (1:10) serum rather than whole blood increases specificity but decreases sensitivity.<sup>45</sup> The CATT can be reliably performed using a micromethod on filter paper or diluted blood, reducing threefold the cost of screening.<sup>44,46</sup>

In Rhodesian HAT, parasitemia is higher and trypanosomes are easier to find in the blood using the methods described previously. Lymph node aspirates are rarely feasible or necessary. Since the disease progresses more rapidly than Gambian HAT, an abnormal CSF WBC or CSF trypanosomes are detected more frequently. There are no antibody-detection assays.

Rare patients diagnosed with late-stage African trypanosomiasis in industrialized countries and investigated with modern tools have been found by magnetic resonance imaging to have hyperintense signal changes in the basal ganglia and deep within gray and white matter as well as meningeal thickening.<sup>47,48</sup> Mediastinal, hilar, and para-aortic lymphadenopathy can be seen on CT scan.<sup>47</sup>

## Differential Diagnosis

The differential diagnosis of early-stage HAT is that of recurrent fever, which is associated with a long list of other diseases in the tropics, foremost among which are malaria, HIV infection, and typhoid. The cervical lymphadenopathy of HAT is softer and smaller than that of tuberculous lymphadenitis and cancer but similar to HIV-associated generalized lymphadenopathy. In late-stage HAT, other causes of chronic lymphocytic meningitis must be considered, especially tuberculous meningitis and HIV-induced opportunistic infections such as cryptococcosis. In tourists with *T. b. rhodesiense* trypanosomiasis, the disease needs to be distinguished from severe malaria and African tick bite fever.

## TREATMENT AND PROGNOSIS

There is probably no other disease for which most currently recommended drugs have been used for 60 years or more<sup>49</sup>: suramin since 1925, melarsoprol and pentamidine since the 1940s.<sup>50</sup> Eflornithine, the only new drug approved for human use, has recently been made widely available through the generosity of the pharmaceutical industry.<sup>51</sup> To select the best treatment for a patient in whom trypanosomes have been found, two questions must be answered: (1) Is it *T. b. gambiense* or *T. b. rhodesiense*? (2) Is the patient in early stage or late stage? The first question is easily addressed by geographic considerations. To answer the second question, an LP must always be performed. Patients with a CSF WBC higher than 5/mm<sup>3</sup> or with CSF trypanosomes are in late stage; all others are in early stage. Intrathecal IgM synthesis has been

proposed as a better test to diagnose late stage disease,<sup>52</sup> but this is unlikely to be available.

Pentamidine is the standard treatment for early-stage Gambian HAT; suramin is less effective; and melarsoprol, though very effective, is not used because of its toxicity. Pentamidine isethionate, given intramuscularly (IM) (or intravenously [IV], but this is impractical in rural hospitals), cures 93% of early-stage patients. Pentamidine injections are exquisitely painful and may result in sterile abscesses. During pentamidine treatment, 1% of patients die. In rural African hospitals, the causes of such deaths are difficult to determine accurately, but potentially severe adverse effects are hypotension, hypoglycemia (during treatment) or diabetes (after treatment), hypocalcemia, hyperkalemia, renal failure, neutropenia, and ventricular arrhythmias.

For late-stage Gambian HAT, eflornithine, a selective and irreversible inhibitor of ornithine decarboxylase and thus of polyamine synthesis, is the drug of choice, but its IV administration every 6 hours is problematic in rural hospitals. It is as effective as melarsoprol but less toxic. The 14-day regimen cures more than 95% of new cases and 98% of postmelarsoprol relapses, presumably because of higher CSF eflornithine levels in the latter.<sup>53,54</sup> For new cases, a 7-day course is clearly inferior to the 14-day regimen.<sup>53</sup> Eflornithine is less effective in HIV-seropositive patients, who should be treated with melarsoprol,<sup>50</sup> and in children, who should be given higher doses (125 to 150 mg/kg every 6 hours for 14 days). The drug also seems to be less effective in patients from Uganda, for reasons that are unclear.<sup>53</sup> For relapsing cases, a 7-day course (same dosage) seems adequate and could be considered in conditions of drug shortage.<sup>53,55</sup> Anemia, leukopenia, and thrombocytopenia are frequent in patients treated with eflornithine but are not clinically significant. Convulsions (6% to 8%) are related to high CSF drug levels, usually subside when the drug is withheld, and do not recur when drug treatment is resumed after 24 to 48 hours. Fatalities (2% to 3%) during eflornithine treatment are probably related to advanced HAT rather than drug toxicity. Oral eflornithine is less effective than IV eflornithine owing to its 55% bioavailability and the osmotic diarrhea it induces if more than 75 mg/kg every 6 hours is given. Nifurtimox, a drug used in the treatment of Chagas disease, cures at most half the patients at the price of substantial toxicity and cannot be recommended.

The trivalent arsenical derivative melarsoprol should be used in cases of late-stage Gambian HAT if eflornithine is not available. It is remarkably effective (94% to 97% cure rate) but very toxic (4% to 6% death rate). It should be given as 10 daily IV injections on successive days, rather than the traditional scheme of three series of three daily injections separated by 1-week drug-free intervals. A randomized trial has shown that these two regimes had comparable efficacy and toxicity<sup>56</sup>; the new regime is preferred because it reduces the duration of hospitalization and the total dose of melarsoprol required. Reactive encephalopathy (4% to 8%, 15% if the CSF WBC is greater than 100/mm<sup>3</sup>) with grand mal seizures, coma, or behavior changes can be a severe, unpredictable complication of melarsoprol treatment. More than half the patients die within 48 hours. Prednisolone reduces by two-thirds the risk of encephalopathy and by half the mortality without increasing the risk of treatment failure.<sup>57–59</sup> It should be given to all melarsoprol-treated patients. Pretreatment with pentamidine

or suramin has been given for decades in the hope of reducing the risk of encephalopathy, but this remains unproved and cannot be recommended. Standard “adjuvant” drugs are anthelmintics (ivermectin, albendazole, or thiabendazole, especially if the patient has strongyloidiasis, to avoid corticosteroid-induced complications) and antimalarials. Encephalopathy should be treated with anticonvulsants (phenytoin, phenobarbital, or diazepam) and IV steroids (dexamethasone or hydrocortisone) to reduce cerebral edema. Dimercaprol (BAL), a heavy metal chelator, is useless and may even be deleterious in the treatment of encephalopathy whose pathogenesis is an immunologic reaction rather than arsenic toxicity.<sup>58</sup> Polyneuropathy (up to 10%) is a direct toxic effect of arsenic, which if neglected can progress to paraplegia or quadriplegia. When a patient complains of paresthesias, melarsoprol should be withheld for a while and thiamine (100 mg three times a day) administered. Tremors are sometimes seen and respond well to  $\beta$ -blockers. Fever can be caused by lysis of trypanosomes, but superinfections should always be sought, especially pneumonia. Cutaneous reactions (1%) can be troublesome. Phlebitis and cellulitis at the injection sites are caused by the propylene glycol solvent.

After treatment, all patients should be followed with an LP every 6 months for 2 years, or sooner if symptoms recur. A relapse is certain if trypanosomes are found in the CSF (rarely in blood or lymph nodes), but most relapses are characterized only by an elevated CSF WBC. Patients should be considered as having postmelarsoprol (or posteflornithine) relapse if their CSF WBC is greater than 50/mm<sup>3</sup> and higher than the previous determination, or if it is 20/mm<sup>3</sup> to 49/mm<sup>3</sup> and higher than the previous measurement with attendant recurrence of symptoms. When in doubt, the LP should be repeated after 1 to 2 months. The trend in the CSF WBC is more important than the absolute value, since many genuinely cured patients have a slightly elevated CSF WBC 6 months after treatment. Patients who relapse after melarsoprol treatment should be given eflornithine (a second course of melarsoprol is usually ineffective)

and vice versa. Patients with a CSF WBC greater than 20/mm<sup>3</sup> after pentamidine treatment are considered to be relapsing. Those with borderline results (6/mm<sup>3</sup> to 19/mm<sup>3</sup>) should be retested earlier than the routine 6-month interval. Patients who relapse after having received pentamidine for early-stage Gambian HAT should be treated with eflornithine or melarsoprol. Surprisingly, the vast majority of late-stage adult patients cured by melarsoprol or eflornithine, even if comatose before treatment, have no obvious sequelae. Children display sequelae more frequently (e.g., poor performance at school).

In early-stage Rhodesian HAT, suramin is the treatment of choice and is superior to pentamidine. A test dose is initially given although anaphylaxis is rare. Several regimens are recommended,<sup>17</sup> but this probably does not matter given the drug's extremely long half-life of approximately 50 days. Melarsoprol would be effective but is avoided because of the risk of encephalopathy. The failure rate with suramin varies from 0% to 31%.<sup>50</sup> Adverse effects are fever, proteinuria, and urticaria. Suramin is 99.7% protein-bound and has no CSF penetration. *T. b. rhodesiense* is resistant to eflornithine. Melarsoprol is the only effective treatment for late-stage patients, having a 95% cure rate. Despite the lack of controlled trials, most authorities recommend starting with a small dose of melarsoprol and increasing it progressively. Pretreatment with suramin is generally advocated on the theoretical grounds that it might prevent seeding of the CSF when the LP is conducted. Several regimens are used; Table 92-1 lists one of those recommended by WHO.<sup>17</sup> Melarsoprol-induced encephalopathy is more common in Rhodesian (5% to 18%) than in Gambian HAT, and mortality during treatment is higher (3% to 12%). Although not studied in such patients, it seems reasonable to administer prednisolone at the same dosage as in Gambian HAT. The same adjuvant drugs should be used, and encephalopathy should be treated along the same lines. Follow-up should be as in Gambian HAT, except that LPs should be carried out every 3 months during the first year. Most patients who relapse after melarsoprol treatment of

**Table 92-1 Treatment Regimens for Gambian and Rhodesian Trypanosomiasis**

	<i>Trypanosoma brucei gambiense</i>	<i>Trypanosoma brucei rhodesiense</i>
Early stage	Pentamidine IM 4 mg/kg up to 300 mg/day for 7 days	Suramin IV 5 mg/kg on day 1, then 20 mg/kg IV (up to 1.0 g) on days 3, 5, 12, 19, 26
Late stage	Eflornithine IV 100 mg/kg q6h for 14 days or Melarsoprol IV 2.2 mg/kg daily for 10 days	Melarsoprol (dose in mg/kg): 1.80 mg/kg (day 5), 2.16 (day 6), 2.52 (days 7, 14), 2.88 (day 15), 3.24 (day 16), 2.9 (day 20), 3.6 (up to 180 mg) (days 23, 24, 25)
Relapses	Postpentamidine: melarsoprol or eflornithine as above; Postmelarsoprol: eflornithine as above; Posteflornithine: melarsoprol as above	Postsuramin: melarsoprol as above; Postmelarsoprol: second course of melarsoprol, 3 × 4 daily injections, all doses at 3.6 mg/kg (up to 180 mg)
Melarsoprol-induced encephalopathy		
Prevention	Prednisolone 1 mg/kg up to 40 mg/day, started 1–2 days before first dose of melarsoprol, continued until last dose, tapered over 3 days (30, 20, 10 mg)	As in <i>T. b. gambiense</i>
Treatment	Anticonvulsants, IV corticosteroids	As in <i>T. b. gambiense</i>
Pretreatment	None	Suramin 5 mg/kg on day 1, 20 mg/kg on day 3
Adjuvant drugs	Antimalarials, anthelmintics	As in <i>T. b. gambiense</i>

Rhodesian HAT are cured by a second course of the same drug. For those who relapse a second time, a combination of melarsoprol and nifurtimox might be considered. For Gambian HAT patients who relapse after two separate treatments with melarsoprol and eflornithine, the best option is probably the simultaneous administration of eflornithine and melarsoprol at maximal dosage.<sup>60</sup>

Given the lack of financial incentives, it appears unlikely that new drugs will be developed for HAT in the near future, although one possible new prodrug DB289 [2,5-bis(4-amidinophenyl)furan-bis-O-methylamidoxime] has completed Phase I clinical trials and is about to enter Phase II<sup>49</sup> (see also <http://www.sti.ch/scih/africa1.htm>). A high priority should be given to studies of combinations of drugs such as melarsoprol-eflornithine or melarsoprol-nifurtimox, which might allow shorter, less toxic, treatment.

## PREVENTION AND CONTROL

For Gambian HAT, case finding remains the cornerstone of disease control. Infected individuals can remain asymptomatic and contagious for months or years before developing overt sleeping sickness, and they become less contagious when CNS involvement progresses, since trypanosomes are then found more in the CSF than in the bloodstream. The only way to break the chain of transmission is to identify and treat asymptomatic persons. Populations of endemic foci should be examined twice a year by mobile teams. Previous case-finding surveys based only on detection and aspiration of cervical lymphadenopathy gave excellent results when 95% or more of the inhabitants were present. If only 50% of the population participates, as is often the case nowadays,<sup>61</sup> and if only this traditional method is used, not enough carriers will be identified to modify the epidemic dynamics. However, use of the CATT to identify suspects on whom parasitologic assays are concentrated doubles the number of parasitemic persons detected (half of whom have no lymphadenopathy) and will compensate for the lower participation.

The best approach is to perform the CATT on all inhabitants. CATT-positive subjects should have blood examinations (ideally the mAECT, or at least a thick and a wet smear) and lymph node aspiration if feasible. Most control programs treat only persons in whom trypanosomes have been seen. Whether the systematic treatment of individuals with a positive CATT and negative parasitologic assays would lead to more rapid disease control is unknown, but it seems that many such individuals have merely transiently positive CATT assays as a result of infection with trypanosomes that are not pathogenic for humans.<sup>62</sup> Pentamidine “chemoprophylaxis” of the whole population of endemic areas would not be acceptable today because of its adverse effects and the risk of transmission of blood-borne pathogens, and certainly no traveler is at sufficiently high risk of HAT to warrant consideration of individual chemoprophylaxis.

To what extent HAT case finding can be integrated within the activities of multipurpose fixed health centers has been much debated. It is possible to improve the efficacy of passive case detection by rural health centers but not to delegate to them active case finding.<sup>63</sup> The subjects in most cases passively detected by health centers already have an abnormal CSF, and their treatment must have only a modest impact on transmission.

Vector control by tsetse fly trapping is a useful adjuvant, but its cost is such that it is not sustainable on a large scale and should be considered only for high-incidence villages. Given the lack of commercial potential and the capacity of the parasite to undergo continuous antigenic variation, it is unlikely that an antitrypanosome vaccine will ever be developed. For Rhodesian HAT, the recent experience of the Uganda national control program showed that a major epidemic can be controlled through surveillance and case detection by sleeping sickness orderlies, combined with intensive tsetse fly trapping.<sup>64</sup> The performance of national control programs should be closely monitored through predetermined indicators.<sup>65</sup>

# American Trypanosomiasis (Chagas' Disease)\*

LOUIS V. KIRCHHOFF

## INTRODUCTION

American trypanosomiasis (Chagas' disease) is a zoonosis caused by *Trypanosoma cruzi*, a protozoan parasite found only in the Americas. The geographic range of *T. cruzi* infection in humans and other mammalian hosts is primarily determined by the distribution of the various species of blood-sucking triatomine insects that act as its vectors. This range extends from the southern United States to Central Argentina. Although major portions of the range of *T. cruzi* lie in temperate regions, Chagas' disease is generally considered a tropical disease because the majority of infected persons live in the tropics.

## AGENT

The genus *Trypanosoma* contains about 20 species, but only *T. cruzi* and the two African trypanosome subspecies, *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, cause disease in humans.<sup>1</sup> *Trypanosoma rangeli*, which also is found only in the Americas, can be transmitted to humans, but it does not cause a persistent infection and is not pathogenic.<sup>2</sup> *T. cruzi* was first described in 1909 by the Brazilian physician Carlos Chagas, who saw the motile parasites while doing microscopic examinations of dissected intestines of triatomine insects.<sup>3</sup> The complex life cycle of *T. cruzi* involves insect vectors as well as mammalian hosts (Fig. 93-1). The vectors become infected when they ingest blood from mammals that have circulating trypomastigotes, which are nondividing but infective forms of the parasite (Fig. 93-2). Once inside the midgut of an insect host, the parasites undergo transformation to epimastigotes, which are flagellates having a distinct morphology, and these organisms then multiply extracellularly. After migration to the hindgut, epimastigotes transform into nondividing metacyclic trypomastigotes, which are then discharged with the feces around the time of a subsequent blood meal. Transmission to a second mammalian host occurs when breaks in the skin, mucous membranes, or conjunctivae are contaminated with insect feces containing the infective

**FIGURE 93-1** Eggs, second instar nymph, and adult of *Rhodnius prolixus*, a triatomine vector of *Trypanosoma cruzi*.

metacyclic forms. Inside the new host, these parasites enter a variety of host cell types and, after transformation into amastigotes, multiply intracellularly. When proliferating amastigotes fill the host cell, they differentiate into trypomastigotes and the cell ruptures. The parasites released invade adjacent tissues and spread hematogenously to distant sites where they initiate further cycles of intracellular multiplication. Thus they maintain a parasitemia infective for vectors. *T. cruzi* can also be transmitted by transfusion of blood donated by infected persons,<sup>4</sup> from mother to fetus,<sup>5-7</sup> and in laboratory accidents.<sup>8</sup>

## DISTRIBUTION OF *TRYPANOSOMA CRUZI*

### Epizootiology

Infection with *T. cruzi* is a zoonosis, and involvement of humans in the cycle of transmission is not necessary for

**FIGURE 93-2** *Trypanosoma cruzi* trypomastigote in human blood (Giemsa stain,  $\times 625$ ). (Courtesy of Dr. Maria Shikanai Yasuda, São Paulo, Brazil.)

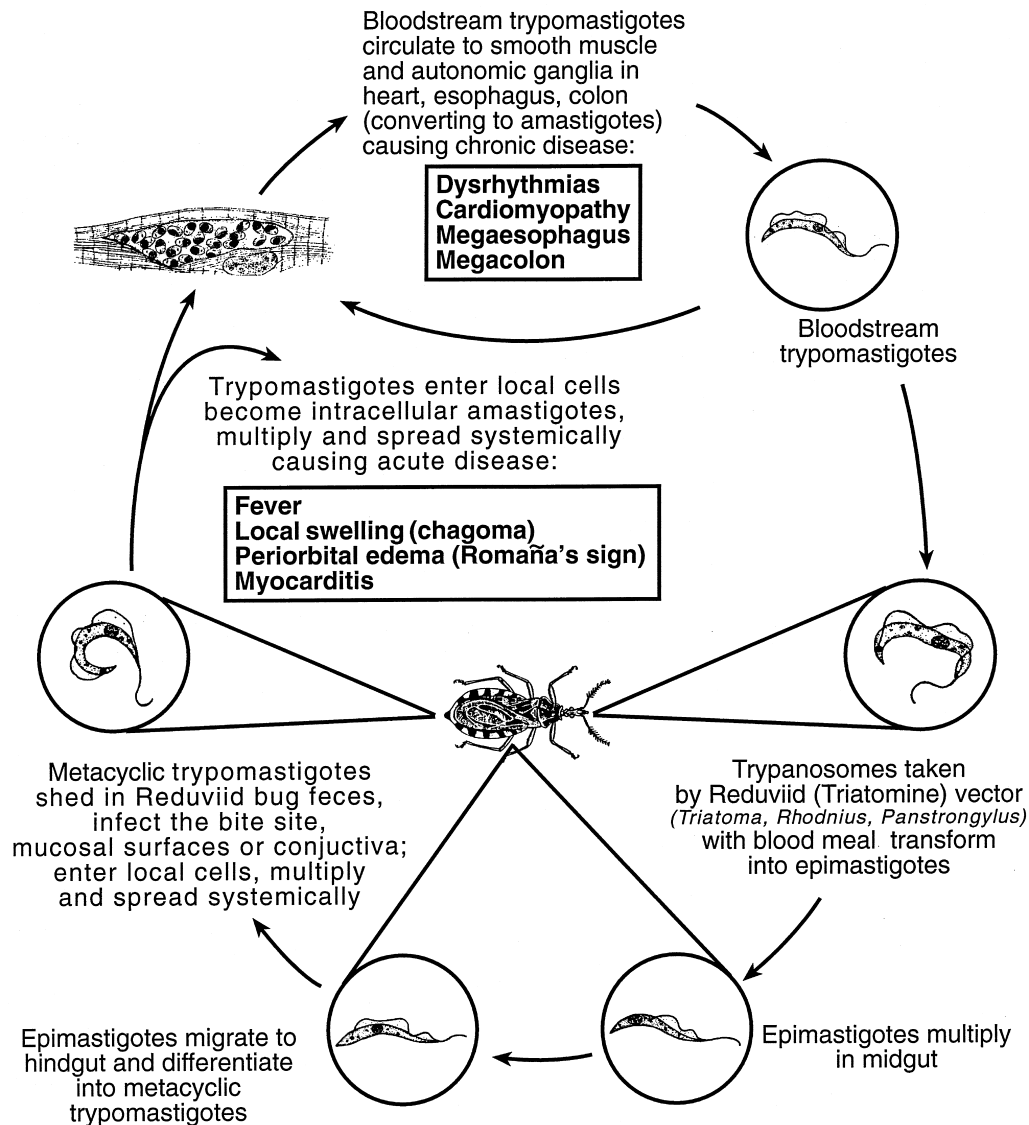

\*All material in this chapter is in the public domain, with the exception of the borrowed figures.

perpetuation of the parasite in nature. *T. cruzi* is found only in the Western Hemisphere, where it primarily infects wild and domestic mammals and insects.<sup>9,10</sup> Triatomine vectors that transmit *T. cruzi* are found in spotty distributions, from central Argentina to the southern half of the United States.<sup>11,12</sup> Hollow trees, burrows, palm trees, and other animal shelters are places where transmission of *T. cruzi* occurs among infected vectors and nonhuman mammalian hosts. Piles of wood, old vegetation, and roof tiles near houses have also been found to harbor large numbers of insects.<sup>13,14</sup> Vector-borne transmission to humans takes place only in areas inhabited by triatomine species that defecate during or immediately after blood meals.

However, this restriction does not apply to transmission to nonhuman mammalian hosts, which can become infected by eating infected insects.<sup>15</sup>

*T. cruzi* has been found in more than 100 species of domestic and wild mammals,<sup>16</sup> from the southern United States<sup>10,17–20</sup> to Central Argentina.<sup>21,22</sup> Opossums, wood rats, armadillos, raccoons, dogs, and cats are typical hosts, but *T. cruzi* is not a problem in livestock. Nontypical hosts can become infected when held in zoos in areas in which *T. cruzi* is enzootic.<sup>23–25</sup> This lack of species-specificity, combined with the fact that infected mammals have lifelong parasitemias, results in an enormous domestic and sylvatic reservoir in enzootic areas.

## Chagas' Disease\* *Trypanosoma cruzi*

\*Reservoir hosts include armadillos, opossums, dogs, cats, rats, and many other mammals

## Epidemiology of Chagas' Disease in Latin America

Historically, humans have become part of the cycle of *T. cruzi* transmission as farmers and ranchers open up land in enzootic regions. When this development takes place, vectors such as *Triatoma infestans*, *Rhodnius prolixus*, and *Panstrongylus megistus* invade the nooks and crannies of the primitive wood, mud-walled, and stone houses that are typical of rural Latin America. In this manner the vectors become domiciliary, establishing a cycle of transmission which involves humans and peridomestic mammals and is largely independent of the sylvatic cycle.<sup>13,26–28</sup> For the most part, Chagas' disease has been a problem of poor people living in rural areas. In recent decades, however, large numbers of infected people have migrated to cities, thus urbanizing the disease and resulting in frequent transmission by blood transfusion prior to the implementation of effective serologic screening.<sup>29–32</sup>

Early reports indicated that most cases of acute Chagas' disease that came to medical attention occurred in children.<sup>33</sup> Prevalence data support this view, but few age-specific and geographic incidence data have been available because most cases of the acute illness go undetected due to its mild nature and the lack of access to medical care among those at highest risk. The Pan American Health Organization estimated that 10 to 12 million people are infected with *T. cruzi* and that roughly 45,000 deaths each year are attributable to Chagas' disease.<sup>34</sup> However, in recent years, the epidemiology of *T. cruzi* infection has improved markedly in several endemic countries, as vector and blood bank control programs have achieved considerable success. As a consequence, prevalence rates in younger age groups have been decreasing in many areas.<sup>35–37</sup>

Note: The epidemiologic database in many areas is limited. Transmission of *T. cruzi* has been interrupted in many large areas in the endemic area (e.g., Argentina, Brazil, Chile, Uruguay). At least 80,000 *T. cruzi*-infected immigrants now reside in the United States.

A major international eradication program in the "Southern Cone" countries of South America (Brazil, Paraguay, Uruguay, Argentina, Chile, and Bolivia) has provided the framework for much of this progress. Uruguay and Chile were certified as transmission-free in 1997 and 1999, respectively. It appears likely that Brazil and Argentina will be certified as transmission-free in 2005 or 2006.<sup>38,39</sup> Similar control programs have been established recently in the Andean countries and in Central America.<sup>40</sup> In Mexico, legislation mandating nationwide blood donor screening is about to be passed, and this reflects a growing awareness of Chagas' disease as a public health problem there.<sup>32,41</sup> The obstacles hindering the elimination of *T. cruzi* transmission to humans throughout the endemic range are economic and political, and no technological advances are necessary for its completion.

The epidemiology of symptomatic chronic Chagas' disease is noteworthy. As many as 70% of persons who harbor *T. cruzi* chronically never develop associated cardiac or gastrointestinal symptoms. Among those who do develop either type of disease, the mean age of onset of symptoms is 35 to 45 years, although the age range is quite broad. In the past, the relatively high frequency of sudden death among young adults in some areas was attributed to arrhythmias due to chronic Chagas' disease, and several decades ago in one highly endemic area of Brazil chagasic cardiac disease was found to be the most frequent cause of death in adults.<sup>42</sup> Among Brazilian patients with chronic *T. cruzi* infection, the prevalence of megadisease has been found to range from 2.6% to 17.3%.<sup>43,44</sup>

Interestingly, there is considerable geographic variation in the relative prevalence of cardiac and megadisease in patients with chronic Chagas' disease. In most South American countries, megadisease is nearly as common as chagasic cardiac disease, but in Colombia, Venezuela, Central America, and Mexico megadisease is virtually unknown. It is not known if host factors or parasite strain differences cause these different patterns of clinical expression of the disease.

## Epidemiology of Chagas' Disease in the United States

Despite the presence of the sylvatic cycle of *T. cruzi* in many parts of the southern and western United States, only five instances of autochthonous transmission there have been reported.<sup>45–47</sup> Our relatively high housing standards and low overall vector density probably underlie the rarity of transmission of *T. cruzi* to humans in the United States. In the past years, seven laboratory-acquired cases of acute Chagas' disease and nine imported infections have been reported to the Centers for Disease Control and Prevention (CDC), but none in the latter group occurred in returning tourists. Although the number of imported and autochthonous cases of acute Chagas' disease may be many times the number reported, the fact remains that the illness is rare in the United States.

In contrast, the number of persons in the United States with chronic *T. cruzi* infections has grown enormously in recent years. It is currently estimated that 12 million persons born in countries in which Chagas' disease is endemic currently live in the United States. Approximately 8 million of these individuals are from Mexico,<sup>48,49</sup> where the overall prevalence of *T. cruzi* infection may be 0.5% to 1.0%.<sup>32</sup> Moreover, a large proportion of these immigrants have come from Central

America, a region in which *T. cruzi* prevalence is high.<sup>30,50,51</sup> A study among Salvadorans and Nicaraguans in Washington, D.C., found a 5% prevalence rate of *T. cruzi* infection.<sup>52</sup> Seroprevalence studies done in a Los Angeles hospital where 50% of donors are Hispanic have shown that between 1 in 1000 and 1 in 500 donors are infected with *T. cruzi*.<sup>53</sup> In another study, carried out in seven blood banks in three southwestern states, roughly 1 in 600 donors with Hispanic surnames were found to be infected.<sup>54</sup> In a much larger study performed in Miami and Los Angeles, the *T. cruzi* prevalence rate was found to be 1 per 8800 in the general donor population and 1 per 710 among donors who had spent a month or more in an endemic area.<sup>55,56</sup> It can be estimated from these findings and census data that there are 80,000 to 120,000 *T. cruzi*-infected people now living in the United States. The presence of these immigrants creates a risk of transfusion-associated transmission of the parasite here, and to date seven such cases have been reported in the United States and Canada.<sup>57</sup> All the reported cases occurred in immunosuppressed patients in whom the diagnosis of *T. cruzi* infection was made because of the fulminant course of the illness. Since most transfusions are given to immunocompetent patients in whom acute Chagas' disease would follow a mild course, it is reasonable to infer that many other instances of transfusion-associated transmission of *T. cruzi* have occurred in the United States and have gone unnoticed. In recent years, however, the risk may have been reduced by screening prospective blood donors with questions relating to Chagas disease.<sup>58</sup> Finally, three recipients of transplants obtained from a *T. cruzi*-infected Central American immigrant developed acute Chagas' disease and one died of the latter illness.<sup>59</sup>

## DISEASE

The clinical manifestations of acute and chronic Chagas' disease are very different and are described separately.

### Acute Chagas' Disease

The first sign of acute Chagas' disease can be a chagoma, which is an erythematous and indurated lesion at the site of parasite entry that appears a week or two after transmission has occurred.<sup>60</sup> When the conjunctiva is the portal of entry, the patient may develop Romaña's sign, which is unilateral and painless periorbital edema (Fig. 93-3). Romaña's sign is found in only a small proportion of patients with acute *T. cruzi* infection and similar findings can be the result of several other processes.

Systemic spread of the parasites from the site of initial multiplication may be accompanied by malaise, fever, and edema of the face and lower extremities, as well as hepatosplenomegaly and generalized lymphadenopathy. A peripheral lymphocytosis may accompany the high parasitemias of acute Chagas' disease, and mild elevation of transaminases may also be present. Muscles, including the heart, can be heavily parasitized, and severe myocarditis with functional impairment occasionally causing death develops in a small proportion of patients<sup>33,46,61</sup> (Fig. 93-4). Nonspecific electrocardiographic (ECG) changes can occur, but the life-threatening conduction defects common in chronic cardiac Chagas' disease are usually not seen. *T. cruzi* also can invade

**FIGURE 93-3** Romaña's sign (unilateral painless periorbital edema) in a Brazilian patient with acute Chagas' disease. (Courtesy of Dr. Mário Shiroma, São Paulo, Brazil.)

the central nervous system,<sup>62</sup> but neurologic findings are not common. Rarely, meningoencephalitis develops, and it is associated with a poor prognosis.<sup>63</sup> In the vast majority of patients, the acute illness resolves spontaneously in 4 to 8 weeks and they then enter the *indeterminate phase* of the infection, which is characterized by a lack of symptoms, subpatent parasitemias, and generally detectable antibodies to a variety of *T. cruzi* antigens.

**FIGURE 93-4** *Trypanosoma cruzi* in the heart muscle of a child who died of acute Chagas' disease. The infected cardiomyocyte shown contains several dozen amastigotes.

## Chronic Chagas' Disease

### Chronic Chagas' Cardiopathy

Although most persons with chronic *T. cruzi* infections remain in the indeterminate phase for life, approximately 10% to 30% develop symptomatic chronic Chagas' disease, usually years or even decades after the infection was initially acquired. Cardiac problems are the most frequent complications of chronic Chagas' disease.<sup>64,65</sup> Hearts obtained at autopsy from patients who died of chagasic heart disease usually have a global appearance due to chamber enlargement, which is often greater on the right than the left. Mural thrombi are frequently present, often in the right atrium and the apex of the left ventricle. Left ventricular apical aneurysm is typical in patients with advanced cardiac Chagas' disease. At a cellular level, the process that underlies these gross pathologic lesions is a chronic inflammation with mononuclear cell infiltration and diffuse fibrosis that affects the conduction system as well as the cardiac muscle.<sup>66,67</sup> Parasites are rarely seen on histological examination, but they can often be detected by polymerase chain reaction–based assays.<sup>68</sup> The process results in a variety of dysrhythmias, including atrial bradyarrhythmias and fibrillation; premature ventricular contractions; bundle branch blocks, often of the right bundle; and complete atrioventricular block. Most instances of sudden death in persons with chronic *T. cruzi* infection probably result from complete atrioventricular block, ventricular tachycardia, or ventricular fibrillation.

The symptoms associated with chronic cardiac Chagas' disease reflect the congestive failure, rhythm disturbances, and thromboembolism that result from the fibrosing cardiopathy.<sup>69</sup> The arrhythmias can cause dizziness and syncope, and sudden death is a common occurrence.<sup>42,70</sup> The cardiomyopathy frequently affects the right side of the heart more than the left, and thus symptoms of right-sided failure are often present. The progression of chagasic arrhythmias and cardiomyopathy is gradual, but once congestive heart failure develops, death often occurs within several months.

### Chronic Gastrointestinal Chagas' Disease (Megadisease)

Dysfunction of the gastrointestinal tract is the second most common consequence of chronic *T. cruzi* infection.<sup>71,72</sup> As in the case of chagasic cardiopathy, gastrointestinal Chagas' disease usually occurs years or even decades after infection with *T. cruzi* is acquired. Dysfunction related to megaesophagus (Fig. 93-5) is the most typical clinical manifestation, but symptoms due to megacolon (Fig. 93-6) are also frequent. Other gastrointestinal and urinary viscera can be affected as well, but this is much less common.<sup>73</sup> The process underlying megadisease is a loss of neurons in the gut.<sup>74</sup> Quantitative assessments of this degenerative process have shown that in severely affected patients as many as 85% of the neurons in the esophagus and 50% of those in the colon may be lost. The factors that determine the rate and pattern of the neuronal destruction are not known.

Pathologic examination of esophageal specimens obtained surgically or at autopsy from patients with megaesophagus have shown dilation and varying degrees of thickening of the

**FIGURE 93-5** Barium esophagogram in a Brazilian patient with dolichomegaesophagus caused by chronic Chagas' disease. Contrast material is pooled in the distal esophagus, which is markedly enlarged. (From Neva FA, Brown HW: Basic Clinical Parasitology, 6th ed. Norwalk, CN, Appleton & Lange, 1994.)

**FIGURE 93-6** Barium enema examination of a patient with megacolon caused by Chagas' disease. Markedly increased diameter of the ascending, transverse, and sigmoid segments of the large bowel are marked with opposing arrows.

muscular wall. As in the case of cardiac tissue, microscopic examination shows mononuclear cell infiltration and fibrosis, but finding parasites is unusual. The most common symptom associated with chagasic megaesophagus is dysphagia. Many patients experiencing this sense the accumulation of swallowed food in the esophagus and take in water or more food, or even eat in a standing position, to facilitate its passage into the stomach. Pain, typically starting in the lower substernal area and spreading upward, is also a frequent symptom in patients with megaesophagus. In patients with severe degrees of megaesophagus, regurgitation can become a problem, and if the underlying problem is not treated, it can lead to intermittent aspiration with associated chronic cough, bronchitis, and pneumonia.

As in the case of chagasic megaesophagus, colonic disease is manifested by dilation and thickening of the wall. Typically, the sigmoid colon is the most affected segment. As the disease progresses, the colon can become markedly enlarged in both length and diameter, and the thickening of the wall can become less pronounced. The pathologic changes evident on microscopic examination of affected colonic tissue are similar to those found in the esophagus. The cardinal symptom associated with Chagas' disease of the colon is constipation. As the size of the colon increases gradually over years, the frequency of bowel movements decreases, and some patients can go for several weeks without bowel movements. Pain is also a common symptom, resulting from accumulation of feces and flatus, as well as ineffective and recurrent colonic contractions.

Other organs also can be affected by chronic gastrointestinal Chagas' disease. The most common occurrence is hypertrophy of the parotid glands, which is present in as many as 25% of patients with chagasic megaesophagus. The stomach may also be affected, although much less commonly than the colon and esophagus, and affected patients usually have either megaesophagus or megacolon.<sup>75</sup> Hypoperistalsis, hypotonia, decreased acid secretion, and delayed emptying of the stomach have been documented in patients with megaesophagus, but dilation of the stomach is not found frequently.<sup>76</sup>

The pathogenesis of the cardiac and gastrointestinal lesions of chronic Chagas' disease has been debated for decades.<sup>77-79</sup> Recently, convincing evidence has accumulated supporting the concept that low-level presence of parasites in chronically affected cardiac tissue, detectable by molecular methods, stimulates a chronic inflammatory response that over time leads to the pathologic changes observed microscopically.<sup>80,81</sup>

### ***Trypanosoma cruzi* Infection in Immunosuppressed Patients**

Immunosuppression of persons who chronically harbor *T. cruzi* can lead to a recrudescence of the infection, frequently with an intensity that is atypical of acute Chagas' disease in immunocompetent patients. The incidence of reactivation of *T. cruzi* in patients who become immunosuppressed is not known, and both its occurrence<sup>82-84</sup> and its absence<sup>85,86</sup> have been reported. Persons immunosuppressed by the human immunodeficiency virus (HIV) and infected with *T. cruzi* are also at risk for reactivation of the latter. To date, several dozen such cases have been described,<sup>87-92</sup> and it is noteworthy that

many of these patients developed *T. cruzi* brain abscesses, which do not occur in immunocompetent persons with acute or chronic Chagas' disease. The diagnosis of *T. cruzi* brain abscesses in HIV-positive patients is complicated by the fact that these lesions are difficult to distinguish radiographically from those of cerebral toxoplasmosis.

## **DIAGNOSIS**

The approaches used to diagnose acute and chronic Chagas' disease are quite different and will be considered separately.

### **Acute Chagas' Disease**

The first step in diagnosing acute Chagas' disease is determining that the patient has a history consistent with exposure to *T. cruzi*. Risk factors include residence or a blood transfusion in an endemic country, birth to a mother known or suspected of being infected with *T. cruzi*, or a laboratory accident involving the parasite. When considering geographic risk, it is important to bear in mind that there have been no reports of imported cases among tourists returning to the United States from countries in which Chagas' disease is endemic. Two such cases in tourists returning to Europe, however, have been described.<sup>93,94</sup> It is also worthy of note that only five cases of autochthonous transmission of *T. cruzi* have been described here, and the most recent of these occurred in 1998.<sup>47</sup>

Patients with acute Chagas' disease may develop a variety of local and systemic signs, but these are usually mild. Occasionally, severe myocarditis develops, leading to nonspecific ECG changes, radiographic signs of cardiomegaly, or pericardial effusion detectable by echocardiography. Invasion of the central nervous system by the parasites can lead to abnormal cerebrospinal fluid values. The differential diagnoses of all of these clinical findings are quite broad, however, and in the absence of a parasitologic diagnosis they can only be viewed as suggestive of Chagas' disease.

A definitive diagnosis of acute Chagas' disease is made by detecting parasites, and serologic assays for *T. cruzi*-specific IgM, which are neither standardized nor widely available, are of limited importance.<sup>95</sup> Circulating trypomastigotes are highly motile and frequently can be seen in wet preparations of anticoagulated blood or buffy coat. The parasites often can be seen in Giemsa-stained smears as well. In immunocompetent patients with acute Chagas' disease, examination of blood preparations is the cornerstone of detecting *T. cruzi*. In immunocompromised patients suspected of having acute Chagas' disease, however, other specimens such as bone marrow, lymph node aspirates, endomyocardial tissue, skin lesion biopsies, cerebrospinal fluid, and pericardial fluid should be examined microscopically. When these methods fail to detect organisms in any patient with clinical and epidemiologic histories suggesting a diagnosis of acute Chagas' disease, as is often the case,<sup>96,97</sup> efforts to grow the parasites can be undertaken. This is done by culturing blood or other specimens in specialized liquid medium<sup>98,99</sup> or by xenodiagnosis, which is a method employing laboratory-reared insect vectors.<sup>100</sup> A major drawback to these approaches is the fact that they take a minimum of several weeks to complete, and this is far

beyond the time at which decisions regarding drug treatment need to be made. In addition, although blood culture and xenodiagnosis are more sensitive than microscopic examination of blood and other specimens, their sensitivities in detecting *T. cruzi* in acutely infected patients have not been determined. Hemoculture for *T. cruzi* infection is available in my laboratory. Xenodiagnosis is not done in the United States.

### Chronic Chagas' Disease

As mentioned previously, patients with chronic cardiac Chagas' disease can develop a variety of dysrhythmias, including right bundle branch block, which is the most representative conduction abnormality of Chagas' cardiopathy. Nonetheless, it is a nonspecific finding and especially in nonendemic countries the vast majority of persons with right bundle branch block do not have Chagas' disease. Echocardiographic and radiographic signs of chronic cardiac Chagas' disease are similar to those found in patients with heart failure due to cardiomyopathies caused by other processes. Megacolon and megaesophagus are best diagnosed by barium contrast radiographic tests. It is important to keep in mind, however, that all of these diagnostic studies are useful primarily for defining the degree of associated abnormalities in patients known to be infected with the parasite.

Chronic Chagas' disease is usually diagnosed by detecting IgG antibodies that bind specifically to parasite antigens, and isolating the organism is not of major importance. At the present time, about 30 assays for the serologic diagnosis of *T. cruzi* infection are available commercially. Most of these are based on enzyme-linked immunosorbent assay (ELISA), indirect immunofluorescence, and indirect hemagglutination formats, and they are used widely in Latin America for clinical testing and for screening donated blood.<sup>101</sup> Several tests are based on recombinant antigens.<sup>102–104</sup> Many of the assays have sensitivities and specificities that are less than ideal, and false positive reactions typically occur with samples from patients having illnesses such as leishmaniasis, syphilis, malaria, and other parasitic and nonparasitic diseases. Because of these shortcomings, most authorities recommend that samples be tested in two or three assays based on different formats before decisions regarding infection status are made. This additional testing, however, carries with it an enormous economic and logistical burden, particularly in regard to donated blood. As an example, in the largest blood donor center in São Paulo, Brazil (Hemocentro, 22,000 donations/month), two tests for antibodies to *T. cruzi* are employed and 1.1% of donated units are discarded because of reactivity in one or more of the assays (E. Sabino, São Paulo, Brazil, personal communication, 2004). As many as two thirds of these donations may have come from persons who are not infected with *T. cruzi*, but whose blood must be discarded because of inconsistent test results. Clearly more accurate tests for detecting chronic *T. cruzi* infection are needed. Some years ago a lysate-based ELISA (Chagas' Kit, Hemagen Diagnostics, Inc., Columbia, MD) was cleared by the Food and Drug Administration (FDA) for clinical testing [510(k)] but not for screening donated blood. Within the past year, an ELISA based on recombinant antigens (Chagatest ELISA Recombinante v3.0, Wiener Laboratories, Rosario, Argentina) was also cleared by the FDA for clinical testing. Two other tests have received 510(k) clearance

(Chagas EIA, Abbott Laboratories, Abbott Park, IL,<sup>105</sup> and Chagas' IgG ELISA, Meridian Diagnostics, Inc., Cincinnati, OH<sup>101</sup>), but neither is currently marketed in the United States.

The possibility of using PCR assays for detecting *T. cruzi* infection has been the focus of considerable study. Although the numbers of parasites in the blood of chronically infected persons is extremely low, PCR assays have the potential for detecting their presence because they have large numbers of highly conserved nuclear and kinetoplast DNA (kDNA) sequences. Moser and coworkers<sup>106</sup> described a PCR assay in which a 188-base pair nuclear repetitive DNA sequence is amplified using primers called TCZ1 and TCZ2. Each parasite contains approximately 100,000 copies of this sequence, and in contrived experiments as little as 0.5% of the genome of a single organism gave a positive result. A study in mice with acute and chronic *T. cruzi* infections indicated clearly that TCZ1-TCZ2 assay is much more sensitive than microscopic examination of blood.<sup>107</sup> In another PCR assay, described by Sturm and coworkers,<sup>108</sup> a 330-base pair segment of the *T. cruzi* kinetoplast minicircle is amplified using primers S35-S36. It is estimated that each parasite has 120,000 copies of this sequence, and in mixing experiments the authors detected 0.1% of one parasite genome. To date, two head-to-head comparisons of the TCZ1-TCZ2 and S35-S36 assays have been described, and in both cases the TCZ1-TCZ2 test appeared to have a slight edge in terms of sensitivity.<sup>107,109</sup> PCR assays for *T. cruzi* detection based on several other primer pairs have been described but none appears to have any advantage over tests based on TCZ1-TCZ2 and S35-S36, probably because the parasite has fewer copies of the DNA sequences they amplify.

Since these two original reports were published in 1989, more than 100 articles have appeared that deal with the detection of *T. cruzi* by PCR tests. In nine key human studies published in the 1990s, the sensitivities of the PCR assays ranged from 44.7% to 100%, with most results falling a bit over 90%.<sup>98,99,110</sup> These disappointing results are likely the result of a sampling phenomenon in that the large numbers of amplifiable sequences are not dispersed, but rather are contained in the rare parasites that may or may not be swept up with blood drawn for testing. Clearly the level of sensitivity achieved with PCR assays for *T. cruzi* infection is not high enough to allow their use for confirmatory testing of donated blood. Nonetheless, PCR assays are potentially useful for detecting *T. cruzi* in persons with borderline serologic results, in persons suspected of having acute or congenital Chagas' disease in whom parasites are not detected microscopically, and in infected patients who have received specific treatment. In such individuals, only positive PCR results can be taken as truly indicative of infection status. No PCR test for detecting *T. cruzi* is currently available commercially.

Parasitologic diagnoses of chronic *T. cruzi* infections also can be made by xenodiagnosis and hemoculture. As noted, xenodiagnosis is not available in the United States. When done properly, hemoculture, which is available in my laboratory, may have a sensitivity as high as 70% in persons with chronic *T. cruzi* infections.<sup>98</sup> Its use should be limited to patients suspected of having acute or congenital *T. cruzi* infection who are negative by microscopic examination of blood and to persons who may have chronic Chagas' disease whose serologic studies are indeterminate.

## TREATMENT AND PROGNOSIS

### Antiparasitic Drugs

Therapy for *T. cruzi* is unsatisfactory and the need for a parasitologically curative drug regimen is the most important current challenge in Chagas' disease research. Many dozens of drugs have been tested for activity against *T. cruzi*, including those active against other parasitic protozoans, and only two have been found to be clinically useful.<sup>111,112</sup> The first of these is nifurtimox (Lampit, Bayer 2502), a nitrofur derivative with which extensive clinical experience has accumulated during the three decades it has been available.<sup>113</sup> Its mechanism of action is not known.

In patients with acute Chagas' disease, nifurtimox reduces the severity and duration of the illness and lessens mortality. Parasitologic cures are achieved with nifurtimox only in approximately 70% of these patients. Those not cured enter the indeterminate phase of *T. cruzi* infection and are at risk of symptomatic chronic Chagas' disease. In general, cure rates are less than 20% in patients with chronic *T. cruzi* infection. Nifurtimox must be taken for long periods and can cause severe side effects, including gastrointestinal complaints such as nausea, vomiting, abdominal pain, anorexia, and weight loss.<sup>114</sup> Some patients taking the drug also develop neurologic symptoms, such as restlessness, insomnia, twitching, paresthesias, polyneuritis, and seizures. Treatment with nifurtimox should be initiated as early as possible in patients with acute Chagas' disease. In the case of a laboratory accident with a reasonable likelihood of transmission, therapy should be started before parasitologic or clinical signs of infection become apparent.<sup>8,115</sup> Nifurtimox is available in 30- and 120-mg tablets. For adults, the recommended oral dosage is 8 to 10 mg/kg body weight per day. For adolescents, the dose is 12.5 to 15 mg/kg/day, and for children 1 to 10 years of age, it is 15 to 20 mg/kg/day. The drug should be given each day in four divided doses, and treatment should be continued for 90 to 120 days. Nifurtimox can be obtained from the CDC Drug Service (770-639-3670).

The drug of choice for treating *T. cruzi* is the nitroimidazole derivative benznidazole (Radimil, Roche 7-1051).<sup>116</sup> Cure rates are similar to those of nifurtimox.<sup>117</sup> Side effects can include granulocytopenia, rash, and peripheral neuropathy. The recommended oral dosage of benznidazole is 5 mg/kg body weight per day for 60 days.

The question of whether patients in the indeterminate or chronic symptomatic phases of *T. cruzi* infection should be treated is controversial. The fact that parasitologic cure rates are so low is a central issue in this debate. Recent studies in *T. cruzi*-infected laboratory animals and humans suggest that the persistent presence of organisms in heart muscle is associated with inflammation, thus implicating the parasites in the chronic pathogenesis.<sup>68,80,118,119</sup> Moreover, limited studies in humans have shown that the appearance and/or progression of cardiac lesions in drug-treated patients may be less than in untreated controls.<sup>117</sup> After reviewing these and other studies, a panel of experts convened several years ago by the World Health Organization recommended that all persons in the indeterminate phase of *T. cruzi* infection should be given drug therapy, and that patients with symptomatic Chagas' disease, hepatic impairment, renal disease, or pregnancy should not.<sup>120</sup> This recommendation stimulated a lot of debate and currently

there is no consensus regarding the treatment of asymptomatic persons with long-standing *T. cruzi* infection.<sup>121,122</sup>

Some authors have pointed out that there is no convincing evidence that specific treatment affects long-term clinical outcome.<sup>123</sup> Recent reports of long-term studies indicating that, in adults, cure rates with nifurtimox and benznidazole are less than 10% have added fuel to the debate.<sup>124-126</sup> Cure rates may be considerably higher in children.<sup>127</sup> Finally, concern relating to these two drugs is raised by reports of experiments showing that 33% of rabbits treated with nifurtimox and 42% of those given benznidazole developed lymphomas, whereas none of the control animals developed tumors.<sup>128,129</sup> Although these findings should be a cause for concern, it should be kept in mind that these two drugs have been used for decades in endemic countries and no reports of an increased incidence of lymphomas have appeared.

Several other compounds merit comment. Some years ago it was shown that recombinant interferon- $\gamma$  (IFN- $\gamma$ ) reduced the severity of acute *T. cruzi* infection in mice.<sup>130</sup> To my knowledge, only two patients with acute Chagas' disease have been treated with IFN- $\gamma$ . The first was an immunosuppressed recipient of a contaminated blood transfusion<sup>131</sup> and the other acquired the infection in the laboratory. Both patients were given nifurtimox in addition to IFN- $\gamma$  and recovered. The person infected in the laboratory was antibody- and PCR-negative 10 years after the incident and the infection status of the immunocompromised patient has not been assessed. Since most patients resolve the acute illness in a matter of weeks even without drug treatment, my view is that nifurtimox or benznidazole should be used alone in immunocompetent patients. Whether IFN- $\gamma$  should be given in addition in immunocompromised patients remains an open question.

The activities of allopurinol and the antifungal agents itraconazole, ketoconazole, and fluconazole against *T. cruzi* have been studied extensively in laboratory animals and to a lesser extent in infected persons. None of these agents has shown a level of anti-*T. cruzi* activity that justifies its use in humans. Posaconazole, which was recently approved by the FDA for treating fungal infections, has been shown to cure *T. cruzi* infections in mice.<sup>132</sup> Efficacy trials in monkeys and humans infected with the parasite are being planned. Other promising drugs are being evaluated.<sup>133-135</sup>

### Treatment of Clinical Chagas' Disease

Beyond the possible use of antiparasitic drugs, the treatment of both acute and chronic Chagas' disease is symptomatic. Patients with severe acute chagasic myocarditis should be supported, as would any patient with acute congestive cardiomyopathy. In patients with symptomatic chronic Chagas' heart disease, therapy is directed at ameliorating symptoms through the use of cardiotropic drugs and anticoagulants. Pacemakers have been shown to be useful in patients with ominous bradyarrhythmias or heart block.<sup>70</sup>

Cardiac transplantation is an option in patients with end-stage Chagas' heart disease, and more than 100 *T. cruzi*-infected patients have undergone the procedure in Brazil and the United States.<sup>136,137</sup> Reactivated acute Chagas' disease occurred often in the patients transplanted initially in Brazil due to the postoperative immunosuppression, but this has been less of a problem in the last decade or so as smaller doses of

cyclosporine have been used. In addition, the fact that the usual parasitologic methods for detecting acute *T. cruzi* infection were not sensitive detectors of the reactivations and the occurrence of malignant neoplasms was an additional problem.<sup>138</sup> It also merits mention that patients who have had heart transplants for Chagas' disease often develop cutaneous lesions containing large numbers of parasites.<sup>139</sup> One such case has been observed in a *T. cruzi*-infected patient who underwent renal transplantation,<sup>140</sup> but interestingly lesions of this type have not been reported in co-infected persons with HIV/AIDS.<sup>89</sup> The efficacy and toxicity of long-term prophylaxis with either nifurtimox or benznidazole in *T. cruzi*-infected patients after cardiac transplantation have not been assessed. In spite of these problems, the long-term survival of Chagas' patients with heart transplants is greater than that of individuals receiving heart transplants for other reasons, most likely because the lesions of chronic *T. cruzi* infection are often limited to the heart.<sup>141</sup> The frequency with which *T. cruzi*-infected immigrants in the United States are considered for cardiac transplantation will increase over time as this group increases in size and ages.

Megaesophagus associated with Chagas' disease should be treated as is idiopathic achalasia.<sup>73</sup> The best relief of symptoms is achieved by balloon dilation of the lower esophageal sphincter.<sup>142</sup> Patients with megaesophagus who fail to respond to repeated balloon dilation may require surgical treatment.<sup>143</sup> The procedure most often used is wide esophagocardiomyectomy of the anterior gastroesophageal junction, combined with valvuloplasty to reduce reflux. Patients with extreme megaesophagus can be treated with esophageal resection with reconstruction using an esophagogastroplasty. In developed countries, laparoscopic myotomy is being used with increasing frequency to treat idiopathic achalasia, and this relatively simple procedure may become the method of choice for both idiopathic achalasia and Chagas' disease. A possible role for the injection of botulinum toxin is being evaluated.<sup>144</sup>

Patients in the early stages of colonic dysfunction associated with chronic *T. cruzi* infection can be managed with a high-fiber diet and occasional laxatives and enemas. Fecal impaction necessitating manual disimpaction may occur, as can toxic megacolon, which requires surgical intervention.<sup>145</sup> Volvulus is a complication of chagasic megacolon that requires immediate attention. This usually occurs when the lengthened and enlarged sigmoid colon twists and folds on itself, causing a constellation of symptoms. Endoscopic emptying can be done initially in patients without clinical, endoscopic, or radiographic signs of ischemia in the affected segment. Cases that are complicated should be treated with surgical decompression. In either case, however, surgical treatment of the megacolon is ultimately necessary because of the common recurrence of volvulus.<sup>143,146</sup> Several surgical procedures have been used to treat advanced chagasic megacolon, and all of them include resection of the sigmoid as well as removal of part of the rectum.

## PREVENTION AND CONTROL

Since there are no vaccines or chemoprophylaxis for preventing transmission of *T. cruzi*, reducing the number of new cases in Latin America must depend on reducing contact with insect vectors and on serologic identification of infected

blood donors. Elimination of domiciliary vectors is best accomplished by improving housing conditions, spraying of insecticides, and educating at-risk populations. As noted previously, major successes with these approaches have been achieved in several endemic countries.<sup>35</sup> Elimination of the sylvatic reservoirs is not a reasonable goal. In view of the successes of low-technology measures in reducing the transmission of *T. cruzi*, it appears unlikely that the recent major advances in understanding the molecular biology of the parasite and the pathogenesis of Chagas' disease will play a substantive role in the eventual elimination of this public health problem.

Since chronic *T. cruzi* infection carries with it the risk of serious cardiac and gastrointestinal disease, I feel that in industrialized countries immigrants from endemic regions and children of infected mothers should be screened serologically. Identification of infected persons is important because pacemakers have been shown to benefit some patients who develop rhythm disturbances. Infected individuals should have ECGs done every 6 to 12 months with the goal of early detection of rhythm disturbances. The possibility of congenital transmission is another reason for screening.

Tourists from the United States who travel in areas where *T. cruzi* transmission occurs should avoid sleeping in dilapidated dwellings in rural areas and should use insect repellent and mosquito nets to reduce exposure to vectors. Nonetheless, it is important to keep in mind that the risk of acquiring *T. cruzi* infection during short-term residence in an endemic country is extremely low. As noted, a Frenchwoman was reported to have become infected with *T. cruzi* during a several-weeks stay in Colombia, and an Italian tour guide acquired the infection while traveling in Brazil.<sup>93,94</sup> To my knowledge, no incidents of this type have been reported among tourists returning to the United States. People traveling in endemic areas should avoid sleeping in primitive dwellings and should use bed nets and insect repellent to reduce exposure to insects.<sup>147,148</sup> Special precautions for people engaging in outdoor activities in the United States are not warranted. Laboratorians should wear eye protection and gloves when working with *T. cruzi*, and suitable containment should be used for infected insects.<sup>149</sup>

As stated previously, seven instances of transfusion-associated transmission of *T. cruzi* have been reported in the United States and Canada. In all these patients, the courses of acute Chagas' disease were particularly fulminant because of the immunosuppression they were receiving, and this certainly contributed to the definitive diagnoses. Since most transfusions are given to immunocompetent persons in whom acute *T. cruzi* infection would be a mild illness, it is reasonable to infer that many other cases have occurred here but have not been noticed. The question as to how best to avoid transmission of the parasite via transfusion in the United States has been debated since the first instance occurred in 1988. Common sense suggests that if screening is warranted in the endemic countries from which the 12 million immigrants living here have come, then they should be tested when they present for donation here. In some donor centers, prospective donors have been asked questions relating to risk for *T. cruzi* infection, with the purpose of deferring persons at high risk for harboring the parasite. The efficacy of this approach is not known, but related data obtained in the United States.<sup>150</sup> and Brazil<sup>151</sup> suggest that it may not be serving its purpose.

Many blood bank authorities, including staff at the FDA, favor serologic screening of all blood donated in the United States. As noted, no blood screening assay has been cleared as yet by the FDA. It is highly likely that the U.S. blood supply will be screened for *T. cruzi* on a nationwide basis when an acceptable assay comes to market. The cost of screening would be \$50 to \$100 million per year. Limited screening involving regional testing, selective screening of donors having geographic risk, or only testing blood products destined for immunocompromised patients are not likely to be implemented.

# Leishmaniasis

SELMA M. B. JERONIMO  
ANASTACIO DE QUEIROZ SOUSA  
RICHARD D. PEARSON

## INTRODUCTION

*Leishmania* species are members of the family Trypanosomatidae, order Kinetoplastida<sup>1,2</sup> (Table 94-1). They reside as intracellular amastigotes within macrophages in mammals and as extracellular promastigotes in the gut of their insect vectors, phlebotomine sand flies. The clinical manifestations of infection vary as a consequence of the virulence of the infecting *Leishmania* species and the cell-mediated immune responses of their mammalian hosts. Leishmaniasis has historically been divided into three major clinical syndromes: cutaneous, mucosal, and visceral. Each of these encompasses a spectrum of findings, and there is overlap between them. Although specific *Leishmania* species tend to cause one syndrome or another, there are frequent variations making generalizations difficult.

*Leishmania* species are endemic in scattered areas of every continent except Australia and Antarctica (see Table 94-1). Cutaneous leishmaniasis is a problem for residents, refugees, military personnel, and workers in endemic areas of Latin America, the Middle East, Asia, and the Indian subcontinent. Close to 700 cases due to *Leishmania major* have been reported among U.S. military personnel serving in Iraq, with additional cases reported from Afghanistan.<sup>3-5</sup> Many were acquired along the Iraq–Syria or Iraq–Iran borders. Mucosal leishmaniasis due to *Leishmania braziliensis* is endemic in Latin America. Major epidemics of visceral leishmaniasis have been reported in eastern India and Bangladesh,<sup>6,7</sup> among refugees in the Sudan,<sup>8,9</sup> and in cities that have expanded into endemic areas in northeastern Brazil.<sup>10</sup> Visceral leishmaniasis emerged as an important opportunistic disease in people with acquired immunodeficiency syndrome in Spain, southern France, and Italy,<sup>11-16</sup> and it occurs in people who are immunosuppressed following organ transplantation or chemotherapy.<sup>17-19</sup> Finally, viscerotropic leishmaniasis was identified in a group of U.S. troops infected during Operation Desert Storm with *Leishmania tropica*, a species historically associated with cutaneous leishmaniasis.<sup>20</sup>

## AGENT

Lainson and Shaw have classified *Leishmania* species into two subgenera, *Viannia* and *Leishmania*, based on their development in the gut of the sand fly. The subgenus *Viannia* includes *L. braziliensis* and related species that develop in the

hindgut before migrating to the midgut and foregut (peripylaria). The subgenus *Leishmania* includes species that occupy the midgut and foregut only (suprapylaria). Within each subgenus, speciation has historically been based on multiple factors, including geographic distribution, animal reservoir, and sand fly species. Refinements in taxonomy are likely to be made as more is learned about the genetic diversity of the parasites.

Several assays can be used to identify *Leishmania* species. Isoenzyme analysis<sup>21-23</sup> is used at several World Health Organization (WHO) reference laboratories. Other approaches include species-specific monoclonal antibodies,<sup>24</sup> restriction endonuclease digestion of kinetoplast DNA (kDNA),<sup>25</sup> and hybridization with species-specific kDNA probes.<sup>26</sup> Polymerase chain reaction (PCR) assays using species-specific oligonucleotide primers are available in research and some reference laboratories and are the method of choice for speciation.<sup>27-33</sup>

The life cycle is relatively simple.<sup>34</sup> Amastigotes are equipped to live at acid pH within parasitophorous vacuoles in macrophages.<sup>35</sup> They are oval or round in shape and approximately 2 or 3  $\mu\text{m}$  in diameter. Amastigotes have a relatively large, eccentrically located nucleus; a specialized mitochondrial structure, the kinetoplast, which contains a substantial amount of extranuclear DNA in the form of catenated mini- and maxicircles; and a flagellar pocket and flagellum, which lie within the confines of the cell. They multiply by simple binary division. A row of subpellicular microtubules is arrayed under the plasma membrane much like the ribs of an umbrella. In the gut of the sand fly,<sup>36</sup> leishmania live and multiply as extracellular, flagellated promastigotes that vary morphologically from short, stumpy forms to elongated ones ranging from 10 to 15  $\mu\text{m}$  in length and 2 or 3  $\mu\text{m}$  in diameter. A single flagellum extends from the anterior pole. After development in the sand fly gut, which takes approximately 1 or 2 weeks depending on the *Leishmania* species, infectious metacyclic promastigotes migrate to the proboscis.<sup>37,38</sup>

*Leishmania* species are transmitted by female sand flies of the genus *Lutzomyia* in the Americas and *Phlebotomus* elsewhere. Depending on the species, sand flies live in forested areas, rodent burrows, or debris in peridomestic habitats. They are weak fliers, but they can be carried considerable distances if caught in the wind and have been dispersed more than 200 m from the original foci.<sup>39</sup> Sand flies probe with their proboscis to form a venous pool, from which they obtain blood by capillary action. Metacyclic promastigotes obstruct the proboscis of leishmania-infected sand flies, preventing easy aspiration of blood and stimulating the fly to probe even more. Although not well quantified, a relatively small number of promastigotes are thought to be inoculated. Sand fly saliva has been shown to enhance the infectivity of promastigotes by inhibiting the L-arginine-dependent nitric oxide killing mechanism of macrophages.<sup>40,41</sup>

## IMMUNOLOGY

The outcome of leishmanial infection is dependent on a series of complex and only partially understood interactions between *Leishmania* species-specific virulence factors and the genetically determined cell-mediated immune responses of their mammalian hosts.<sup>42-45</sup> An array of cytokines secreted by

In Peters W, Killick-Kendrick R (eds): *The Leishmaniases in Biology and Medicine*. London, Academic Press, 1987, pp 1–120.

lymphocytes and macrophages are involved. Antileishmanial antibodies are present but alone are not protective.

### ***Leishmania*–Macrophage Interactions**

The focus of leishmanial infection is the macrophage, the sole sanctuary for the parasite in mammals. In vitro studies using murine and human mononuclear phagocytes indicate

that promastigotes can bind to several macrophage receptors.<sup>46</sup> Two surface molecules on promastigotes are known to be involved in attachment: a 63-kDa neutral protease (gp63)<sup>47,48</sup> and a lipophosphoglycan (LPG).<sup>49,50</sup> The glycosylation of these molecules varies among *Leishmania* species and with the stage of promastigote development.<sup>37,38</sup> The attachment of promastigotes is mediated by several different macrophage receptors, including the complement receptors

CR1 and CR3, the mannose–fucose receptor, and the receptor for advanced glycosylation end products.<sup>51–55</sup> Promastigotes can bind directly to CR3 or after fixing C3bi on their surface. Some *Leishmania* species activate complement through the alternative pathway,<sup>56</sup> and others do so by the classic pathway.<sup>57</sup> With metacyclic promastigotes,<sup>37,38</sup> complement activation occurs at a distance from the cell membrane,<sup>58</sup> the membrane attack complex (C5b–C9) is not inserted, and the parasite is not lysed. After attachment to one or more receptors, promastigotes are phagocytosed by macrophages.

A landmark observation was that human and murine macrophages could be activated by interferon- $\gamma$  (INF- $\gamma$ ) or other macrophage-activating cytokines to kill intracellular amastigotes.<sup>59,60</sup> INF- $\gamma$  was subsequently shown to activate a number of oxidative and nonoxidative microbicidal mechanisms. Studies in murine macrophages in vitro and in mice in vivo indicate that L-arginine-dependent nitric oxide production plays a central role in the killing of leishmania amastigotes.<sup>61–64</sup> Analysis of the macrophage activation pathways suggests that this is due to tumor necrosis factor- $\alpha$  (TNF- $\alpha$ )-dependent

sustained induction of nitric oxide synthase by INF- $\gamma$ .<sup>65</sup> Macrophage antileishmanial microbicidal mechanisms can also be activated in a leishmania-specific manner by direct contact with CD4+ cells bearing surface-bound TNF- $\alpha$ .<sup>66,67</sup>

### Cellular and Cytokine Responses

The immunology and immunogenetics of leishmaniasis have been extensively studied using inbred strains of mice. The susceptibility to *Leishmania donovani* was found to be determined by the *Lsh/lty/BCG* gene on mouse chromosome 1, which was later designated *Nramp* (natural resistance-associated macrophage protein)<sup>65,68–70</sup> and more recently solute carrier 11a1 (*Slc11a1*).<sup>71</sup> *Slc11a1* is a proton/bivalent cation antiporter that is localized in the late endosome and lysosome and controls resistance to intracellular pathogens.<sup>71</sup> This gene also determines susceptibility to *Salmonella typhimurium* and *Mycobacterium* species. *Nramp* has multiple pleiotropic effects. It controls the priming and activation of macrophages

for antimicrobial activity and the differential expression of the early response gene *KC*.<sup>65</sup>

Unfortunately, the genetic determinants of human leishmaniasis have not been defined. The manifestations of disease and outcome of infection clearly vary among different people. For example, it is apparent from studies in Africa<sup>72</sup> and Brazil<sup>73,74</sup> that only a minority of those infected with *L. donovani* or *Leishmania infantum/chagasi* develop progressive visceral disease. The rest have asymptomatic or mildly symptomatic, self-resolving infections.

In both *L. major*-infected mice and humans infected with *L. donovani* or *L. infantum/chagasi*, resolution of leishmanial infection and protection against reinfection are associated with expansion of leishmania-specific CD4+ T cells of the Th1 subtype that secrete INF- $\gamma$  in response to leishmanial antigens.<sup>42–44,75–78</sup> As discussed previously, INF- $\gamma$  can activate macrophages to kill intracellular amastigotes. In the murine model, INF- $\gamma$  also inhibits the development of leishmania-specific, disease-enhancing CD4+ Th2 cells.<sup>75,76</sup> Leishmania amastigotes can inhibit the production of interleukin (IL)-1 and TNF- $\alpha$  by infected macrophages, but INF- $\gamma$  can prime macrophages to produce IL-1 and TNF- $\alpha$  in response to the parasite.<sup>78</sup>

Humans with acquired immunity to *L. donovani* typically evidence delayed-type cutaneous hypersensitivity responses to intradermally administered leishmanial antigens resulting in positive leishmanin (Montenegro) skin tests. Their peripheral blood mononuclear cells typically proliferate and secrete INF- $\gamma$  and IL-2 in response to leishmanial antigens in vitro.<sup>79</sup> People with progressive visceral leishmaniasis have high parasite burdens and do not respond to intradermally administered leishmanial antigens. Their peripheral blood mononuclear cells do not produce INF- $\gamma$  or IL-2 when incubated with leishmanial antigens in vitro.<sup>79</sup>

Data from the murine model and humans suggest that the development of potentially protective Th1 responses is inhibited during progressive infection. In susceptible strains of mice with progressive *L. major* infection, leishmania-specific CD4+ T cells of the Th2 subtype that secrete a panel of lymphokines, including IL-4, dominate during progressive disease. IL-4 was initially thought to play a critical role in suppressing the development of protective Th1 responses,<sup>75–80</sup> but the disease progressed in the usual manner in mice in which the IL-4 gene was knocked out.<sup>81</sup> Another study found that disruption of the IL-4 gene inhibited progression of *Leishmania mexicana* but not *L. donovani* infection.<sup>82</sup> In humans with progressive visceral leishmaniasis, expansion of disease-enhancing, IL-4-secreting, CD4+ T cells of the Th2 subtype has not been documented. Instead, IL-10 appears to be the dominant suppressive cytokine. Messenger RNA (mRNA) for IL-10 has been documented in the bone marrow of people with progressive visceral leishmaniasis,<sup>83</sup> and elevated levels of IL-10 have been found in their serum.<sup>84</sup>

Cytokines produced by macrophages appear to be important early in infection. IL-12 appears to play an important role in promoting the development of protective Th1 responses.<sup>85</sup> IL-12 stimulates natural killer (NK) cells,<sup>86</sup> and they in turn produce INF- $\gamma$ , which can activate macrophages to kill leishmania and primes macrophages to produce IL-1 and TNF- $\alpha$  when they encounter the parasite. In the murine model, CD8+ cytotoxic/suppressor cells may also contribute to protection

by secreting INF- $\gamma$ .<sup>77</sup> Protective cell-mediated immune responses to *L. major* depend on the CD40–CD40 ligand signaling process that mediates IL-12 secretion.<sup>87</sup> However, CD40–CD40 ligand costimulation does not seem to be the only signal required for IL-12 secretion.<sup>88</sup> An alternative mechanism possibly involves the interaction of the TNF family molecule TRANCE and its receptor.<sup>89</sup>

On the other side of the balance are IL-10 and transforming growth factor- $\beta$  (TGF- $\beta$ ),<sup>90</sup> which are produced by macrophages, block the development of Th1 cells, and stimulate the proliferation of leishmania-specific Th2 cells. Leishmanial infection of macrophages also decreases expression of MHC class I and class II molecules<sup>91</sup> and increases macrophage secretion of potentially immunosuppressive prostaglandins and leukotrienes.<sup>92,93</sup> Other factors may also influence the outcome of infection, such as the size of the infecting inoculum. A small inoculum seems to predispose to a protective immune response, whereas a larger one favors progressive disease.<sup>94,95</sup>

An unresolved issue is whether individual parasite antigens preferentially elicit protective or disease-enhancing responses when presented in the context of MHC class II molecules. Studies of the T cell receptor repertoires of inbred strains of mice infected with *L. major* suggested that the same immunodominant parasite epitopes preferentially activated Th1 cells in strains that healed or Th2 cells in those that had progressive disease.<sup>96</sup> In contrast, studies of peripheral blood mononuclear cells from *L. braziliensis*-infected humans showed variations in the cytokine responses to 83- and 70-kDa heat shock proteins, suggesting that leishmanial antigens may vary in their propensity to elicit protective or disease-enhancing responses.<sup>97</sup> Finally, data from the murine system suggest that T cell subsets may be differentially activated when antigens are presented by different antigen-presenting cells, such as macrophages or B lymphocytes.<sup>98</sup>

A discussion of the immunology of leishmaniasis is not complete without a review of the clinical and histopathologic findings observed in the variants of human cutaneous leishmaniasis. People with cutaneous or mucosal leishmaniasis have evidence of both Th1 and Th2 lymphocytes in their lesions, but the systemic response is predominantly Th1.<sup>99</sup> Their peripheral blood mononuclear cells proliferate and produce INF- $\gamma$  and IL-2 in response to leishmanial antigens in vitro, and those infected exhibit delayed-type cutaneous hypersensitivity responses as evidenced by positive leishmanin skin tests in vivo. Complex chemokine and cytokine responses govern the tissue localization of effector cells and the resulting immune responses,<sup>100,101</sup> but the precise sequence of events that results in skin necrosis and eventual healing has not been characterized.

In some respects, the spectrum of cutaneous leishmaniasis is similar to that of leprosy. In diffuse cutaneous leishmaniasis, disease-enhancing factors seem to dominate in the skin, and lesions can persist for decades. They are characterized by macrophage predominance and large numbers of amastigotes, analogous to lepromatous leprosy. Patients have negative leishmanin skin tests and their peripheral blood mononuclear cells do not proliferate or produce INF- $\gamma$  in response to leishmanial antigens.<sup>102</sup>

Patients with destructive mucosal leishmaniasis due to *L. braziliensis* are somewhat analogous to patients with

lepromatous leprosy. Chronic mucosal lesions are characterized by a mononuclear cell infiltrate, lymphocyte predominance, and rare amastigotes. Patients have vigorous delayed-type hypersensitivity responses as evidenced by positive leishmanin skin tests.<sup>103</sup> There is a mixture of Th1 and Th2 cytokines in the lesions, with a striking predominance of mRNA for IL-4,<sup>104</sup> whereas circulating peripheral blood mononuclear cells produce large amounts of INF- $\gamma$  in response to parasite antigens in vitro.<sup>103</sup>

In simple cutaneous leishmaniasis, lesions evolve from macrophage predominance with relatively large numbers of amastigotes in macrophages early in infection to lymphocyte predominance with sparse parasites and granuloma formation later.<sup>105,106</sup> Consequently, in contrast to leprosy, the biopsy findings in leishmaniasis are not predictive of the clinical variant of cutaneous leishmaniasis.

These observations and data from animal models illustrate the complexity of the immune responses elicited by leishmania and the difficulties in generalizing from one *Leishmania* species to another or from animal models to humans. Nevertheless, much has been learned, and it is likely that unifying explanations will emerge in the future and provide the basis for rational approaches to immunoprophylaxis and therapy.

## EPIDEMIOLOGY

WHO estimates that 350 million people are at risk of leishmaniasis worldwide.<sup>107</sup> The true incidence and prevalence are uncertain because of the large number of undiagnosed cases, the lack of screening, and underreporting. The incidence of cutaneous disease is estimated to be 1.0 to 1.5 million cases per year, and the incidence of visceral leishmaniasis is estimated to be 500,000 cases per year. *Leishmania* species are endemic in 82 countries—21 in the New World and 61 in the Old World<sup>108</sup> (see Table 94-1). Detailed descriptions of their geographic locations, reservoirs, and sand fly vectors are available elsewhere.<sup>1,2</sup> Rarely, transmission occurs in utero or at the time of birth,<sup>109,110</sup> as a result of blood transfusion,<sup>111,112</sup> by direct person-to-person contact,<sup>113</sup> or as a consequence of a laboratory accident.<sup>114,115</sup>

### New World Cutaneous and Mucosal Leishmaniasis

Cutaneous leishmaniasis in the Americas is caused by *L. mexicana*, *L. amazonensis*, *L. braziliensis*, *L. panamensis*, *L. guyanensis*, *L. peruviana*, and several other species, including *L. infantum/chagasi*, which is more commonly associated with visceral leishmaniasis.<sup>116–118</sup> For most *Leishmania* species in the New World, the reservoirs are forest-dwelling rodents and other mammals. Dogs and other canines are reservoirs for *L. peruviana* and *L. infantum/chagasi*. The vectors are arboreal or ground-dwelling *Lutzomyia* species.<sup>119</sup> Humans become infected when they work, visit, or live in endemic areas. Large outbreaks have occurred among military personnel,<sup>120</sup> road builders, and agricultural workers who enter or clear forested areas. All of the *Leishmania* species endemic in the Amazon basin are zoonoses, and sylvatic mammals serve as reservoirs. Some of these mammals have survived agricultural development by adapting to peridomestic habitats.<sup>121</sup>

*Leishmania mexicana* is found from Oklahoma and Texas in the north, where several autochthonous cases have been

reported,<sup>122,123</sup> to Argentina in the south. Occasionally, *L. mexicana* is isolated from people with diffuse cutaneous leishmaniasis. *Leishmania amazonensis* is found in forested areas in the Amazon basin. It produces simple cutaneous leishmaniasis but also diffuse cutaneous leishmaniasis and visceral leishmaniasis.<sup>124</sup> *Leishmania infantum/chagasi*, an important cause of visceral leishmaniasis in South America, has been isolated from people with simple cutaneous lesions in Central America.

*Leishmania braziliensis* is a common cause of cutaneous leishmaniasis in Latin America. A small percentage of those infected later develop mucosal leishmaniasis. *Leishmania panamensis* is endemic in Central America and was an important problem among U.S. military personnel when they trained in jungle areas of Panama.<sup>125</sup> *Leishmania pifanoi*, *L. guyanensis*, and *L. venezuelensis* cause cutaneous leishmaniasis in focal areas of South America.

### Old World Cutaneous Leishmaniasis

*Leishmania major* and *L. tropica* are responsible for most of the cases of cutaneous leishmaniasis in the Mediterranean littoral, the Middle East, the Indian subcontinent, and central Asia, whereas *L. aethiopica* is endemic in Ethiopia and adjacent areas of Africa.<sup>126</sup> Occasionally, *L. donovani* or *L. infantum/chagasi* are isolated from cutaneous lesions. *Leishmania donovani* can also produce post-kala-azar dermal leishmaniasis, which is discussed later.

*Leishmania major* is endemic in rural desert areas of the Middle East, southern Russia, Iran, Iraq, and elsewhere in Central Asia. Close to 700 cases of cutaneous leishmaniasis

- *Leishmania (L.) aethiopica*

\**L. tropica* caused cutaneous and viscerotropic disease among troops in Saudi Arabia in the Persian Gulf War.

have been reported among U.S. military personnel serving in Iraq.<sup>3-5</sup> Cases have also been diagnosed in personnel stationed in Afghanistan and Kuwait. *Leishmania major* has also been reported from sites in sub-Saharan West Africa. It typically causes “wet” lesions that tend to be exudative and relatively large. The reservoirs include gerbils, jirds, and other rodents that live in burrows with *Phlebotomus papatasi* or other *Phlebotomus* species. People become infected when they enter endemic areas for military, agricultural, recreational, or other activities. In the past, cutaneous leishmaniasis was a major problem for troops fighting in the Sinai Desert<sup>36</sup> and in the war between Iran and Iraq.

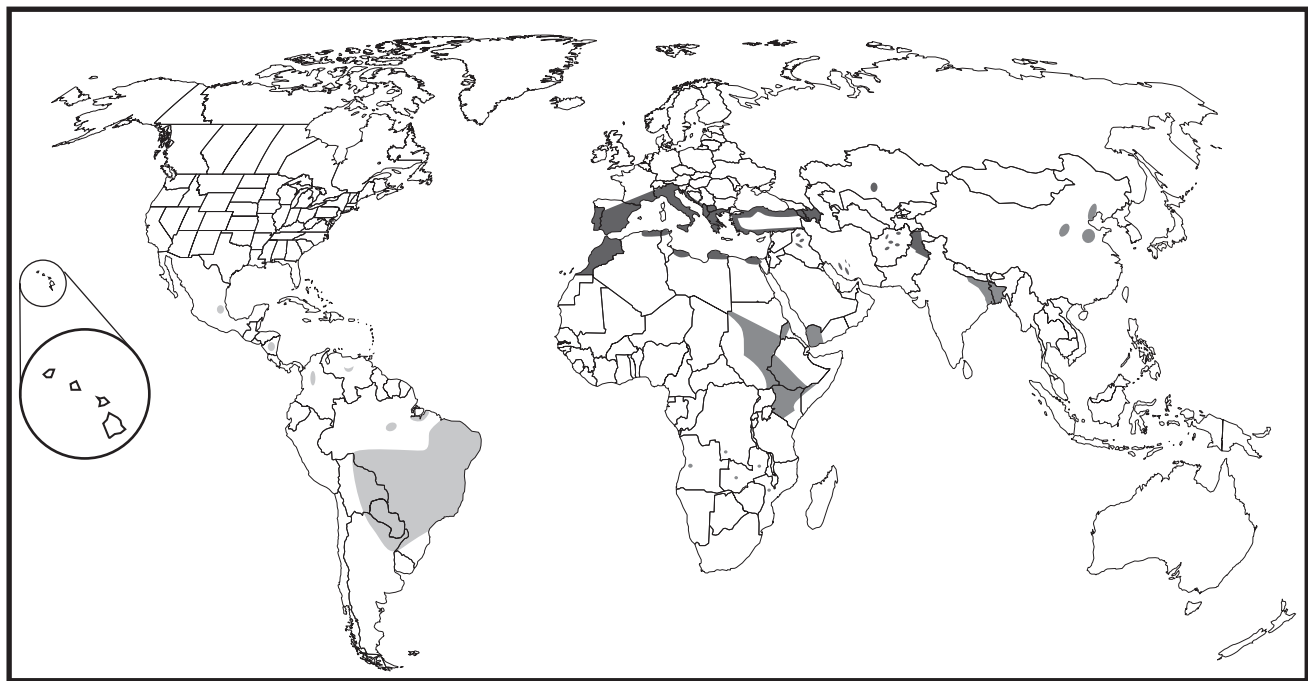

*Leishmania tropica* is endemic in urban areas of the Middle East, the Mediterranean littoral, India, Pakistan, and Central Asia extending into western China. The lesions are usually “dry” with a central crust. In some people, *L. tropica* results in leishmaniasis recidiva, a chronic skin lesion that can persist for decades. The principal reservoirs are dogs and humans. *Phlebotomus papatasi*, *Phlebotomus sergenti*, and *Phlebotomus chadaudi* are vectors.

*Leishmania aethiopica* is endemic in the Ethiopian highlands and Kenya, where it produces simple cutaneous and diffuse cutaneous leishmaniasis.<sup>127</sup> Hyraxes serve as reservoirs. *Phlebotomus longipes* and *Phlebotomus pedifer* are vectors.

#### Visceral Leishmaniasis

In India and East Africa, visceral leishmaniasis is typically caused by *L. donovani*; in the Mediterranean littoral, Middle East, Central Asia, and western China by *L. infantum/chagasi* or *L. donovani*; and in Latin America by *L. infantum/chagasi*. Cases of visceral leishmaniasis are most common among residents of those areas but occasionally occur among travelers and military personnel. Two such cases were reported among U.S. military personnel serving in Afghanistan. Occasionally, *Leishmania* species that are primarily associated with cutaneous leishmaniasis, such as *L. amazonensis* in Latin America<sup>124</sup> and *L. tropica*<sup>128</sup> in the Middle East or India, are isolated from patients with visceral leishmaniasis. For example, a small number of troops infected with *L. tropica* during Operation Desert Storm developed a viscerotropic syndrome.<sup>20</sup>

*Leishmania donovani* is a major problem in eastern India, particularly in Assam and Bihar states, and in Bangladesh.<sup>6,7</sup> Major epidemics have occurred there since the discontinuation of residual DDT spraying for malaria years ago. *Phlebotomus argentipes*, an anthropophilic sand fly, is the vector, and humans serve as the reservoir. People with post-kala-azar dermal leishmaniasis may serve as the reservoir during interepidemic periods.<sup>6</sup> Historically, children and young adults were the

### Visceral Leishmaniasis

- *Leishmania (L.) chagasi*
- *Leishmania (L.) donovani*
- *Leishmania (L.) infantum*

most frequently affected, but more recent data indicate that the mean age has increased to 20 years, possibly related to a decline in herd immunity.<sup>129</sup> *Leishmania donovani* is also endemic in eastern Africa. It is responsible for sporadic cases of visceral leishmaniasis in Ethiopia, Somalia, Kenya, and adjacent countries, and it has caused a major epidemic of visceral leishmaniasis among refugees in the Sudan.<sup>8,9,130</sup> *Phlebotomus orientalis* is thought to be the vector. Rats, gerbils, ground squirrels, and small carnivores are potential reservoirs.

*Leishmania infantum/chagasi* is endemic in scattered areas extending from France, across the Mediterranean littoral,<sup>131</sup> to the Middle East and into western China.<sup>132,133</sup> Canine species are the major reservoirs. Most cases occur in children or immunocompromised adults. Visceral leishmaniasis has been an important opportunistic infection among people with HIV infection in southern France, Spain, and Italy.<sup>11–13,15,16</sup>

*Leishmania infantum/chagasi* is the principal cause of visceral leishmaniasis in Latin America.<sup>73,74</sup> It is endemic in northeastern Brazil and in other widely scattered areas of South and Central America. Children are the most commonly affected; 80% of cases occur in children younger than age 10 years. Sporadic cases occur in endemic regions, but epidemics have been reported in cities that have expanded into rural endemic areas.<sup>10</sup> *Lutzomyia longipalpis* and other *Lutzomyia* species are the vectors. Domestic dogs and wild foxes are thought to be the major reservoirs, although the clustering of cases in households suggests that humans may also serve as a reservoir.<sup>74</sup>

### CLINICAL MANIFESTATIONS

A spectrum of findings is observed within each of the three major clinical syndromes: cutaneous, mucosal, and visceral leishmaniasis. Each of these syndromes is associated with more than one *Leishmania* species, and any given species is capable of producing more than one syndrome. Variations are common, particularly among people who are concurrently infected with HIV or other immunosuppressive illness.

### Cutaneous Leishmaniasis

The typical lesion of cutaneous leishmaniasis develops at the site where promastigotes are inoculated by an infected sand fly. Promastigotes are taken up by mononuclear phagocytes, convert to amastigotes, and multiply within them. Additional mononuclear cells are recruited to the area, and a nodule develops. It enlarges slowly and then ulcerates. Multiple lesions may be present in the same patient. The morphology of the cutaneous lesions is quite variable, and it is not possible to make a species-specific diagnosis based on their characteristics.<sup>127,134</sup>

Depending on the location, Old World cutaneous leishmaniasis is known locally as Oriental sore, bouton d'Orient, bouton de Crete, bouton d'Alep, bouton de Briska, Aleppo evil, Baghdad boil, and Delhi boil. In Latin America, it is variously known as pian bois (bush yaws), uta, and Chiclero's ulcer.

There is substantial variation in the morphology of the lesions. The classic wet lesion of *L. major* is "pizza-like," with

a raised outer border, granulating base, and overlying white, purulent exudate. This type of lesion is also seen with *L. braziliensis* in Latin America. In the dry lesions due to *L. tropica* in the Middle East or India, the ulcer tends to be smaller and covered with a crust. In leishmaniasis recidiva, which is associated with *L. tropica* infection in the Middle East, skin lesions on the face or extremities enlarge slowly while healing in the center. They can persist for decades. Contiguous mucosal involvement is observed in some patients. Some leishmanial lesions are papular, acneiform, nodular, or volcano-like with minimal or no ulceration. Cutaneous lesions persist for months, and in some cases years, before they heal, leaving flat, atrophic scars as evidence of disease. Once a lesion has resolved, the person is usually left with immunity against the infecting *Leishmania* species.

Biopsies of cutaneous lesions demonstrate a spectrum of findings ranging from a predominance of macrophages containing abundant intracellular amastigotes to a predominance of lymphocytes with granuloma formation and few identifiable parasites.<sup>105,106</sup> There appears to be a balance between protective and disease-enhancing mononuclear cell populations in the lesions,<sup>104</sup> but eventually protective elements dominate, amastigotes are cleared, and the lesions heal.

Peripheral lymphadenopathy is observed in some geographic locations. A subset of people infected with *L. braziliensis* develop regional adenopathy, fever, and constitutional symptoms before the skin lesion(s) appears.<sup>135,136</sup> The constitutional findings and the adenopathy resolve as the skin lesion enlarges. In other patients there is involvement of local lymphatics in a sporotrichoid pattern.<sup>134,137</sup> Old World cutaneous leishmaniasis is much less commonly associated with sporotrichoid presentations, although cases have been reported from the Middle East.<sup>138</sup> Necrotizing lymphadenitis has also been reported with *L. major* infection.<sup>139</sup>

Rarely, *L. amazonensis* or *L. braziliensis* disseminates, producing large numbers of cutaneous lesions, often in association with mucosal disease. The lesions tend to be papular or acneiform with few ulcers. This can occur in patients with no demonstrable immune defect or in patients with acquired immunodeficiency syndrome (AIDS).<sup>140</sup> Diffuse cutaneous dissemination of *L. major* has also been associated with AIDS.<sup>141</sup>

Diffuse cutaneous leishmaniasis is an uncommon, anergic variant of cutaneous leishmaniasis that is frequently associated with *L. aethiopica* infections in Africa,<sup>142,143</sup> *L. mexicana* or *L. amazonensis* infections in Central and South America,<sup>144,145</sup> and a separate *Leishmania* species in the Dominican Republic.<sup>146</sup> It begins with a localized lesion that does not ulcerate. Amastigotes progressively disseminate to macrophages in other areas of skin forming cutaneous nodules or plaques. Diffuse cutaneous leishmaniasis with visceral dissemination has also been reported in a patient with AIDS in the West Indies.<sup>147</sup>

Cutaneous leishmaniasis should be considered in the differential diagnosis of subacute or chronic skin lesions in people who have lived, worked, or traveled in endemic areas. The differential diagnosis includes cutaneous fungal infections, such as paracoccidioidomycosis, histoplasmosis, sporotrichosis, chromomycosis, lobomycosis; lupus vulgaris (*Mycobacterium tuberculosis*),<sup>148</sup> *Mycobacterium ulcerans*, and other atypical mycobacterial infections; yaws, syphilis, and leprosy; cutaneous neoplasms; and cutaneous sarcoidosis.

## Mucosal Leishmaniasis (Espundia)

A small percentage of people infected with *L. braziliensis* and occasionally with other *Leishmania* species develop mucosal lesions in the nose, mouth, pharynx, or larynx months to years after resolution of the primary skin lesion. The condition is known in Latin America as espundia.<sup>149–154</sup> Mucosal leishmaniasis often begins with nasal stuffiness and inflammation. Ulceration of the nasal mucosa and septum follows. The lips, cheeks, soft palate, pharynx, and larynx may eventually be involved, resulting in substantial disfigurement and, rarely, aspiration and death. Eustachian tube blockage with secondary middle ear infection has been reported,<sup>155</sup> as well as involvement of the genitalia.<sup>156</sup> Therapeutic failures and relapses are common with traditional pentavalent antimony chemotherapy.

Mucosal involvement is also observed with other *Leishmania* species, although the pathophysiology may be somewhat different. Destructive involvement of the nose and mouth has been reported with *L. tropica* in Saudi Arabia.<sup>157</sup> Mucosal involvement of the upper respiratory tract, larynx, or oral pharynx has been observed in patients with visceral leishmaniasis in the Sudan<sup>158,159</sup> before and, in some cases, following treatment. In southern Europe, mucosal involvement has been reported rarely in apparently immunocompetent people<sup>160,161</sup> and more frequently in those who are immunosuppressed with neoplasms<sup>162</sup> or AIDS.<sup>163,164</sup> The differential diagnosis of mucosal leishmaniasis includes paracoccidioidomycosis, histoplasmosis, syphilis, tertiary yaws, rhinosporidiosis, leprosy, sarcoidosis, basal cell carcinoma and other neoplasms, intranasal cocaine abuse, and midline granuloma.

## Visceral Leishmaniasis

Visceral leishmaniasis is a spectral syndrome. The majority of infections are inapparent and self-resolving; a subset smolder with mild symptoms.<sup>165</sup> Only a minority progress to full-blown visceral leishmaniasis, or kala-azar, which is characterized by fever, weight loss, hepatosplenomegaly, neutropenia, and hypergammaglobulinemia.<sup>166</sup>

Early epidemiologic studies in Africa<sup>72</sup> indicated that the prevalence of positive leishmanin skin tests in endemic areas was much higher than would be predicted based on the incidence of clinically apparent disease. Subsequently, prospective studies of *L. chagasi* in hyperendemic regions of northeastern Brazil demonstrated that the ratio of inapparent to apparent infection was greater than 6.5:1 in children younger than 5 years of age, the most susceptible group, and increased to 18:1 or higher in older children and adults.<sup>73,74</sup>

The determinants of progressive visceral leishmaniasis remain to be defined. Genetically determined cell-mediated immune responses of the host are probably the most important, as discussed previously. Malnutrition is known to suppress cell-mediated immune responses, and it may contribute to progression to symptomatic visceral leishmaniasis,<sup>167–169</sup> although it did not correlate with the development of disease in one prospective study.<sup>74</sup>

The incubation is typically weeks to several months, but it may be as short as 10 days or as long as several years.<sup>170</sup> The onset of visceral leishmaniasis is usually insidious, but it can be abrupt, with high fever suggesting malaria or another

acute infection. In some cases, symptoms have first become manifest in people who have become immunocompromised years after moving from endemic areas.<sup>171</sup>

Full-blown, progressive visceral leishmaniasis, or kala-azar, is associated with fever, abdominal enlargement, weakness, loss of appetite, and weight loss.<sup>166</sup> The clinical findings are similar with *L. donovani* and *L. infantum/chagasi*. Symptoms may be present for weeks to months before patients come to medical attention in rural, endemic areas. The fever pattern may be intermittent, remittent with twice-daily temperature spikes, or, less commonly, continuous. The spleen is firm, nontender, and over time becomes massively enlarged. There is hepatomegaly; the liver typically has a sharp edge and smooth consistency. Peripheral adenopathy is observed in some patients in the Sudan<sup>9</sup> and occasionally elsewhere.<sup>172</sup> Some patients in India develop hyperpigmentation leading to the name kala-azar, which means “black fever” in Hindi.

The late stages of disease are characterized by malnutrition, severe wasting, and progressive debilitation, which are probably due to secretion of cytokines such as TNF- $\alpha$  and IL-1 by infected macrophages.<sup>173</sup> Stunting, decreased height for age, is seen in children.<sup>74</sup> Peripheral edema may occur late in the disease. Petechiae, ecchymoses, and gingival bleeding may also be observed. Hepatic function can be affected and fulminant hepatitis has been reported.<sup>174</sup> Death is often associated with a secondary bacterial infection, such as pneumonia, septicemia, dysentery, or tuberculosis, or with measles or other viral infection.<sup>175</sup>

Laboratory findings include anemia, neutropenia, thrombocytopenia, eosinopenia, and pronounced hypergammaglobulinemia.<sup>166</sup> The anemia is usually normocytic, normochromic, unless there is concomitant iron deficiency. It appears to be due to a combination of factors, including hemolysis, bone marrow suppression, hemorrhage, hypersplenism, and hemodilution.<sup>176–178</sup> Leukopenia can be profound with white blood cell counts below 1000/mL.<sup>166–179</sup> Eosinopenia is the rule.<sup>166–180</sup> The globulin level can reach 9 or 10 g/dL and is due to polyclonal B cell activation. Circulating immune complexes and rheumatoid factors are frequently present.<sup>181,182</sup> Elevated liver enzymes and bilirubin are noted in some patients.<sup>174–183</sup>

The differential diagnosis of visceral leishmaniasis is broad. When patients present with a subacute or chronic course and splenomegaly, hepatosplenic schistosomiasis, myeloproliferative diseases, and tropical splenomegaly due to chronic malaria must be considered. Other possibilities include miliary tuberculosis, histoplasmosis, brucellosis, subacute bacterial endocarditis, infectious mononucleosis, or prolonged *Salmonella* bacteremia. Patients with more acute presentations must be differentiated from those with malaria, amebic liver abscess, acute Chagas' disease, acute schistosomiasis (Katayama fever), typhoid fever, and other acute bacterial or viral infections.

Visceral leishmaniasis in people with concurrent HIV presents in the typical manner in more than two-thirds of cases, but atypical presentations are common. Splenomegaly may be absent.<sup>13,15,16</sup> Amastigotes can be found in macrophages in virtually any organ. They may be seen in biopsies of the lung or pleura<sup>14,184,185</sup> or larynx<sup>163</sup>; in the mucosa of the mouth, esophagus, stomach, or small intestine<sup>186–190</sup>; or in skin lesions.<sup>191</sup> Aplastic anemia has been the presenting

problem in several cases.<sup>192</sup> Asymptomatic leishmanial infections in patients with HIV infection have also been documented.<sup>193</sup> In addition, *Leishmania* species that commonly cause cutaneous disease, such as *L. braziliensis*, can disseminate in the setting of AIDS.<sup>194</sup>

Viscerotropic leishmaniasis was reported in a small group of U.S. military troops infected with *L. tropica* during Operation Desert Storm.<sup>20</sup> They presented with low-grade fever, malaise, fatigue, and, in some instances, diarrhea. Although some had enlarged spleens, none demonstrated massive hepatosplenomegaly, wasting, or the progressive deterioration observed in patients with classic kala-azar. Similar visceralizing *L. tropica* infections have been reported in civilians living in endemic regions.

### Post-Kala-Azar Dermal Leishmaniasis

A subset of people with visceral leishmaniasis in India<sup>3,195</sup> and Africa<sup>196,197</sup> develop skin lesions following treatment, ranging from hyperpigmented macules to frank nodules. Skin lesions typically appear in India 1 or 2 years after treatment and may persist for as long as 20 years. In the Sudan they usually appear at the end or within 6 months of therapy and persist for only a few months to 1 year. Persistence of lesions beyond 1 year is associated with high antileishmanial antibody titers and negative leishmanial skin test responses.<sup>197</sup> The skin lesions contain amastigotes and are thought to be the reservoir of infection during interepidemic periods.<sup>3</sup> Antileishmanial treatment is indicated in Indian post-kala-azar dermal leishmaniasis. In a few instances in India, visceral leishmaniasis has recurred in patients with post-kala-azar dermal leishmaniasis. The differential diagnosis includes leprosy.<sup>198</sup>

## DIAGNOSIS

### Parasite Identification

Although genus- and species-specific molecular probes are available for use in research settings, the diagnosis of leishmaniasis is most often still confirmed in the clinical setting by identifying leishmania amastigotes in a Wright–Giemsa-stained touch preparations<sup>199</sup> or tissue sections or by isolating the parasite in culture. Amastigotes are seen in macrophages in tissue sections, but they may appear to be extracellular in touch preparations. They must be differentiated from the fungus *Histoplasma capsulatum*, which is of similar size but lacks a kinetoplast, and *Toxoplasma gondii*, which typically is smaller.

*Leishmania* can be grown as promastigotes in a number of culture systems, including Novy, MacNeal, Nicolle (NNN) medium, Schneider's insect medium,<sup>200</sup> and several other tissue culture media to which fetal calf serum has been added. The cultures are incubated at 24 to 26°C to approximate sand fly temperatures. In the United States culture media can be obtained from the Centers for Disease Control and Prevention.

Promastigotes can be seen in cultures within a few days if the infection is heavy, or they may take several weeks to reach detectable levels if it is light. Speciation is available through WHO reference laboratories based on isoenzyme patterns,<sup>21,22</sup>

monoclonal antibodies,<sup>24</sup> or other assays. *Leishmania* can also be identified in tissue or culture by PCR using genus- or species-specific probes.<sup>27–33</sup> In cases of suspected cutaneous leishmaniasis, a biopsy should be obtained from the raised border of the skin lesion after the area is meticulously cleaned.<sup>201</sup> The specimen is then divided into pieces for culture, touch preparation, and histopathology. Sterile saline without a bacteriostatic agent can be injected in the margin of the lesion, aspirated, and cultured as well. Appropriate cultures and tissue studies should be performed in order to assess for the possibility of bacteria, mycobacteria, and fungi that are in the differential diagnosis.

The histopathology of cutaneous leishmaniasis is characterized by acute and chronic inflammatory changes with a predominantly mononuclear cell infiltrate consisting of macrophages, lymphocytes, and plasma cells. There may be focal necrosis of infected macrophages. Early in infection macrophages filled with intracellular amastigotes are prevalent. Over time, parasitized mononuclear cells are eliminated from the lesion and a granulomatous response with epithelioid giant cells evolves. The changes are not diagnostic unless amastigotes are identified either visually or by another assay. The sensitivity of blood cultures for cutaneous or mucosal leishmaniasis has not been fully studied but is probably low. Cultures have been positive in some cases.<sup>136,202,203</sup>

In patients with visceral leishmaniasis, fine-needle aspiration of the spleen for culture and touch preparation yields a diagnosis in 96% to 98% of cases.<sup>204</sup> Although generally safe in the hands of an experienced operator, hemorrhage can occur, particularly if the patient has a coagulopathy. Bone marrow aspiration is not as sensitive, but it is diagnostic in more than half of all cases and preferred by some physicians. In India, cultures of peripheral blood buffy coat may be positive for *L. donovani*. Occasionally, *Leishmania* species that more commonly cause cutaneous lesions are isolated from patients with typical visceral leishmaniasis.<sup>124,128</sup> In patients with concurrent HIV infection, the diagnosis is often made by identifying amastigotes in macrophages in biopsies of the lung or pleura, oral or intestinal mucosa, or other sites.<sup>14,158,184,186–192</sup> Amastigotes may also be identified in aspirates of lymph nodes if lymphadenopathy is present.<sup>205</sup>

## Serology

Antileishmanial antibody titers are typically present in high titer in people with visceral leishmaniasis and at low titer or undetectable in those with cutaneous leishmaniasis. They can be measured by a number of assays. Enzyme-linked immunosorbent assay (ELISA), indirect immunofluorescent tests, and agglutination assays have all been used.<sup>206–211</sup>

The sensitivity and specificity of these tests for the diagnosis of visceral leishmaniasis depend on the infecting *Leishmania* species and the leishmanial antigen used. In general, the highest titers are obtained when the homologous *Leishmania* species is used as the antigen source. Unfortunately, the specificity with crude antigen preparations is limited. Cross-reacting antibodies can develop in patients with Chagas' disease, African trypanosomiasis, malaria, leprosy, tuberculosis, schistosomiasis, or potentially other diseases.

Recently developed assays based on recombinant leishmanial antigens provide comparable sensitivity with greater specificity.

Assays using rK39, a recombinant kinesin-like antigen initially identified in *L. chagasi/infantum*, have proven to be both sensitive and specific for the diagnosis of visceral leishmaniasis throughout the world.<sup>212</sup> Antibodies to rK39 are typically not detectable in people with cutaneous leishmaniasis, other infections, or self-resolving *L. donovani* or *L. infantum/chagasi* infections. Both ELISA and immunochromatographic strip tests using rK39 have been reported to have sensitivities greater than 90% and specificities of 98% or higher for the diagnosis of visceral leishmaniasis due to *L. donovani* and *L. infantum/chagasi*.<sup>213</sup> Although antibodies are usually present in high titer in immunocompetent patients with classic visceral leishmaniasis, they are not always detectable in people with visceral leishmaniasis and AIDS, limiting their sensitivity in that setting. The lower titers of antibodies in people with cutaneous leishmaniasis and the presence of cross-reacting "natural" antibodies at low titers in the sera of people who have never been exposed to *Leishmania* species make current serological tests useless for the diagnosis of cutaneous leishmaniasis.

## Skin Test

The intradermal leishmanin (Montenegro) skin test is positive in the majority of people who have asymptomatic, self-resolving *L. donovani* and *L. infantum/chagasi* infections and in people with cutaneous or mucosal leishmaniasis. The skin test is negative in people with progressive visceral leishmaniasis or diffuse cutaneous leishmaniasis, but it becomes positive in the majority of people who are successfully treated for visceral leishmaniasis. The likelihood of a positive skin test appears to be greatest when the infecting *Leishmania* species is used as a source of antigen.<sup>214</sup> Leishmanin skin test reagents are not approved for use in the United States.

## TREATMENT

### Visceral Leishmaniasis

The treatment of leishmaniasis is in a state of transition. Pentavalent antimonial compounds were considered the treatment of choice,<sup>215</sup> but the development of resistance and substantial untoward effects have limited their use in some areas.<sup>216</sup> Liposomal amphotericin B is the only drug approved by the Food and Drug Administration (FDA) for the treatment of visceral leishmaniasis in the United States.<sup>217</sup> The most recent addition is miltefosine, an orally administered compound, which is now used for visceral leishmaniasis in India, where resistance to pentavalent antimonial drugs has become widespread.<sup>218–220</sup>

Liposomal amphotericin B is generally considered the treatment choice for visceral leishmaniasis in the United States and other industrialized countries.<sup>217</sup> Although expensive, it is highly effective and generally well tolerated. Other lipid-associated amphotericin B preparations also appear to be effective, but they have been less extensively studied and are not FDA approved.<sup>221–223</sup> Amphotericin B deoxycholate has long been known to have excellent antileishmanial activity, but its use has been limited by its toxicity.<sup>224</sup> Liposomal and lipid-associated amphotericin B are less toxic and theoretically attractive for the treatment of leishmaniasis in that

they selectively target delivery of the drug to macrophages, the sole site of leishmanial infection. The manufacturer's recommended dosage for liposomal amphotericin B in immunocompetent people is 3.0 mg/kg body weight daily on days 1 through 5, 14, and 21. Data from India suggest that a total dose of 15 mg of amphotericin B divided over five injections is 97% effective. The cure rate decreases with shorter courses and lower doses. For immunocompromised people, the manufacturer recommends 4.0 mg/kg body weight on days 1 through 5, 10, 17, 24, 31, and 38. The high cost and limited availability of liposomal amphotericin B have largely restricted its use to the United States and other industrialized countries.

For decades, pentavalent antimony (Sbv) was the treatment of choice for visceral leishmaniasis, and it is still used in many endemic areas where antimony resistance is not encountered. The response rate remains high in patients infected with *L. infantum/chagasi* in Latin America and with *L. donovani* in the Sudan.<sup>225</sup> As discussed previously, miltefosine has replaced pentavalent antimonials in India, where resistance is widespread among *L. donovani* isolates.<sup>218–220</sup> Two Sbv preparations are available: sodium stibogluconate (Pentostam) and meglumine antimonate (Glucantime).<sup>215</sup> Meglumine antimonate is used in Latin America and French-speaking countries, and sodium stibogluconate is used elsewhere. Although the bioavailability may vary among lots, these two compounds appear to be comparable when administered on the basis of their Sbv content. Meglumine antimonate contains approximately 8.5% (85 mg/mL) Sbv, whereas sodium stibogluconate contains approximately 10% Sbv (100 mg/mL). The recommended dose is 20 mg Sbv per kilogram body weight per day given intravenously or intramuscularly. This dose should not be exceeded. The recommended duration of treatment is 20 to 28 days.<sup>215</sup> Longer periods of treatment have been used for patients who respond slowly and for the treatment of post-kala-azar dermal leishmaniasis.<sup>226,227</sup>

Although most patients are able to complete a full course of pentavalent antimony therapy, side effects are common. They include nausea, vomiting, abdominal pain, anorexia, myalgia, arthralgia, headache, and malaise. Chemical pancreatitis with elevated amylase and lipase is observed in many patients. Severe, clinically apparent pancreatitis is well documented, particularly among patients with renal failure.<sup>228</sup> Sbv causes dose-dependent electrocardiographic changes that include prolonged Q-T intervals and nonspecific ST-T wave effects that resolve within 2 months after the conclusion of therapy.<sup>229</sup> Sudden death has been observed with doses of Sbv in excess of 20 mg/kg/day, presumably due to arrhythmias. Renal failure is a rare complication.<sup>230</sup>

The most exciting recent advance in the treatment of leishmaniasis has been the development of miltefosine.<sup>218</sup> It is licensed in India and widely used there for the treatment of visceral leishmaniasis.<sup>231,232</sup> Miltefosine was initially developed as an antineoplastic drug. It is a phosphocholine analogue and well absorbed after oral administration. The mechanism of its antileishmanial activity has not been defined, but it is known to interact with membrane constituents and to affect cell signaling pathways by inhibiting protein kinase C and phospholipase C. Miltefosine 100 mg daily in adults for 4 weeks has been reported to cure 97%

of people with visceral leishmaniasis in India. A dose of 2.5 mg/kg/daily for 4 weeks was 95% effective in children ages 2 to 11 years. Miltefosine is associated with mild to moderate nausea, vomiting, and diarrhea and "motion sickness" at higher doses. Elevation of transaminases, BUN, and creatinine has been noted early in therapy, but typically decreases with continuation of the drug. Miltefosine has potential reproductive toxicity, and it cannot be used during pregnancy. Women taking it must use appropriate contraceptive measures. In addition, the number of people treated to date and the period of follow-up after treatment are relatively limited. Additional postmarketing surveillance is needed to exclude infrequent or delayed untoward effects. Finally, although miltefosine resistance has not been a clinical problem, it has been documented in vitro.<sup>233</sup>

Alternative drugs for the treatment of visceral leishmaniasis include amphotericin B deoxycholate and pentamidine isethionate, but both have substantial toxicities. Amphotericin B deoxycholate 0.5 to 1.0 mg/kg body weight can be given either daily or every other day for up to 8 weeks.<sup>234</sup> Amphotericin B must be administered parenterally, and is frequently associated with fever, malaise, weight loss, and nephrotoxicity. Pentamidine isethionate 4 mg/kg body weight daily or every other day for 15 doses is another effective but toxic alternative. Lower doses of pentamidine, 2 mg/kg body weight daily, are in general better tolerated but less effective. Pentamidine can cause vascular collapse if infused too rapidly, and it can cause life-threatening hypoglycemia followed by diabetes mellitus due to pancreatic beta cell injury.<sup>235</sup> Insulin-dependent diabetes is a potentially fatal problem for impoverished populations without access to insulin or refrigeration. Pentamidine is also associated with headache, flushing, nausea, vomiting, abdominal discomfort, and reversible azotemia. It can also produce local inflammation and abscess formation when given intramuscularly.

A number of other drugs have been tried or are under investigation. Parenterally administered paromomycin (aminosidine), an aminoglycoside, has been used alone and in combination with other antileishmanial drugs. A dose of 16 mg/kg/day reportedly cured 89% of patients in one study in India.<sup>236</sup> Paromomycin must be administered parenterally for the treatment of visceral leishmaniasis. Side effects include ototoxicity and nephrotoxicity. The imidazole antifungals also have leishmanicidal activity. Ketoconazole and itraconazole have been reported to be effective in some cases of visceral leishmaniasis,<sup>237–240</sup> but failures are also well documented.<sup>239</sup> Substantial interest was engendered by the development of recombinant interferon (rINF)- $\gamma$ , which in vitro activates macrophages to kill intracellular amastigotes.<sup>241–245</sup> Unfortunately, rINF- $\gamma$  was not curative when used as monotherapy.<sup>246</sup>

Even with effective antileishmanial chemotherapy, the death rate for people with visceral leishmaniasis approaches 10% in some series. Secondary bacterial and viral infections are common and may prove fatal. Patients should be evaluated for secondary infections and promptly treated with appropriate antibiotics. Visceral leishmaniasis can also be associated with severe malnutrition, which must be addressed. Finally, people with visceral leishmaniasis often have evidence of hypersplenism, but splenectomy is not indicated except in the rare case in which signs of hypersplenism persist following treatment.

Unfortunately, there are no rigid criteria to document cure in patients treated for visceral leishmaniasis. Improvement in temperature, sense of well-being, and hematological abnormalities and resolution of hepatosplenomegaly are typically used to assess the clinical response. Treatment does not necessarily result in sterile immunity as indicated by clinical relapses, which usually occur within 6 months of completion of therapy in immunocompetent patients. The development of a positive leishmanin skin test, which tends to occur as early as 6 months to 1 year after chemotherapy, seems to indicate immunity.

The treatment of people with concurrent visceral leishmaniasis and AIDS poses special challenges. The greatest experience to date has been in Spain, southern France, and Italy. The initial parasitological cure rates with pentavalent antimony, amphotericin B deoxycholate, and lipid-associated amphotericin B have been substantially lower than seen in immunocompetent people. Even in people who initially respond, relapse rates are high. Secondary prophylaxis with regularly administered liposomal amphotericin B, pentavalent antimony, or, possibly in the future, miltefosine, seems prudent, but data are lacking to document their efficacy or to aid in the selection of a specific regimen. Highly active antiretroviral chemotherapy has been shown to decrease the likelihood of visceral leishmaniasis developing in people with AIDS and should be initiated as soon as possible in those with concurrent AIDS and visceral leishmaniasis.

### Cutaneous Leishmaniasis

The goal of treatment in cutaneous leishmaniasis is to limit tissue damage and, in the case of *L. braziliensis* and related species, to prevent the later development of American mucosal disease. The natural history of cutaneous leishmaniasis varies with *Leishmania* species. In most instances, the lesions heal spontaneously with time. In general, people with cosmetically inconsequential cutaneous lesions can be followed expectantly, provided that the infection is not due to *L. braziliensis* or related *Leishmania* species that are associated with American mucosal leishmaniasis. People with involvement of the face, those with large lesions, those with diffuse cutaneous leishmaniasis, and those infected with a *Leishmania* species that can produce mucosal leishmaniasis should be treated. Systemic therapy is recommended to prevent later mucosal disease in the latter case, but the efficacy has not been clearly demonstrated.

Pentavalent antimony drugs are used in many settings, but *Leishmania* species vary in their susceptibility. Typically, SbV 20 mg/kg/day is given for 20 days.<sup>215,216</sup> Shorter courses and lower doses have been used, but they may predispose to the development of antimony resistance. Even with successful chemotherapy, lesions typically epithelialize slowly over a period of weeks. The published results are variable. Cure rates with *L. braziliensis* in residents of Brazil or Columbia have been in the range of 60% to 70%, but they were greater than 95% in U.S. troops infected with *L. panamensis* in Panama. In the case of *L. major*, 60% of placebo recipients healed within 20 weeks after seeking medical attention in one study, and 74% of those receiving pentavalent antimony healed within 30 days. A number of other drugs and approaches have been proposed. The imidazole antifungals have variable activity.

Ketoconazole, itraconazole, and fluconazole have been used effectively in some but not all settings. For example, ketoconazole 400 to 600 mg/day for 4 to 8 weeks was reported to be effective in approximately 70% of people with *L. major* and *L. mexicana* infections, but it was less effective against *L. tropica*, *L. aethiopica*, and *L. braziliensis*.<sup>247,248</sup> Fluconazole (200 mg daily for 6 weeks) was superior to placebo in people with cutaneous leishmaniasis due to *L. major* in Saudi Arabia.<sup>249</sup> At the end of the treatment period, 60% of placebo recipients were cured versus 90% of the fluconazole-treated group. The published experience with miltefosine is still limited.<sup>250</sup> In an open-label trial in Columbia, treatment of soldiers with 50 to 100 mg per day for 21 days cured 66%; higher doses of 133 to 150 mg/day cured 94%, but 40% of recipients developed motion sickness. Vomiting and diarrhea occurred on 2% of treatment days. The results were promising, but the number of subjects treated was small. Allopurinol was reported to be effective in one study, but its use has been questioned.<sup>251</sup> A number of other drugs have been reported to have antileishmanial activity, but many of the studies have had relatively small sample sizes and were not done in a controlled, blinded manner. Given that spontaneous healing occurs with visceral leishmaniasis, it is impossible to formulate recommendations from uncontrolled studies.

Topical therapy has been another approach. The application of 15% paromomycin and 12% methylbenzethonium has been used successfully in a subset of patients with cutaneous leishmaniasis in Israel and Guatemala.<sup>252,253</sup> Intraleisional injections of antimony have also been used to treat *L. major*. Typically, 0.5 to 2.0 mL (100 mg/mL) is injected around all sides of a lesion until it blanches. When 10 such injections were administered on alternative days to Egyptian patients, 85% were cured at 3-month follow-up. The cure rate with cryotherapy in the same study was 73%.

Other approaches have been tried. Immunotherapy with a combination of leishmania promastigote antigens and live bacille Calmette-Guérin (BCG) has been used effectively in Venezuela and Brazil, but the time to clinical response is relatively long.<sup>254</sup> Patients in Guatemala with cutaneous leishmaniasis and in the Dominican Republic with diffuse cutaneous leishmaniasis have been successfully treated with locally applied heat,<sup>255</sup> although the treatment requires close monitoring. In diffuse cutaneous leishmaniasis, an anergic variant that responds poorly to SbV, combined therapy with SbV and rINF- $\gamma$  was reported to be successful.<sup>256</sup> Leishmaniasis recidivans is another variant that responds poorly to most forms of therapy, although some success has been achieved with intraleisional injections of SbV with or without systemic SbV therapy.

### Mucosal Leishmaniasis

Mucosal leishmaniasis due to *L. braziliensis* is usually treated with a SbV, 20 mg/kg for 28 days, but only 60% of patients have clinical responses, and relapses are observed in up to 30% of cases in Brazil.<sup>24,150,257,258</sup> Amphotericin B has been used as an alternative as well as pentamidine, 2 to 4 mg/kg once or twice a week until the lesions clear.<sup>249,259–261</sup> Miltefosine and liposomal amphotericin B are potential future treatment possibilities, but they have not been studied in this setting. The combination of SbV plus rINF- $\gamma$  was reported to

work in a limited number of cases.<sup>262</sup> Plastic surgery may be necessary for cosmetic purposes in people with mucosal leishmaniasis, but it should be delayed for at least 1 year after clinically apparently successful chemotherapy because skin grafts are likely to be lost if infection relapses.

## PREVENTION

Leishmaniasis can be prevented by interrupting sand fly transmission or by removing or treating reservoirs of infection. It is hoped that in the future it will be prevented by immunization, but no vaccine is currently available.

The short-term visitor to an endemic area should use personal protective measures to avoid sand fly bites. Sand flies tend to bite from dusk to dawn. The application of DEET (diethyltoluamide)-containing insect repellents to exposed skin and under pant and shirt cuffs, the use of fine-mesh screens or insect nets, and the application of insecticide (usually permethrin or other pyrethroids) to clothing and bed-nets<sup>263–265</sup> decrease the risk of transmission of leishmaniasis as well as malaria and other diseases transmitted by sand flies and mosquitoes.<sup>262</sup> Unfortunately, these measures are often not practical or affordable for local residents.

Residual insecticide spraying is effective where transmission occurs in the domestic or peridomestic setting, but the use of residual insecticides has been limited by concern for the environment, cost, and potential evolution of resistance among sand flies and other arthropod vectors. It is of historical note that the use of residual DDT for malaria control following World War II was credited with dramatic reduction in the transmission of leishmaniasis in India, Bangladesh, and southern Iran.<sup>265–267</sup> Epidemics of visceral leishmaniasis subsequently followed the discontinuation of spraying. Residual insecticides have also been used successfully in other locations where transmission is peridomestic. One novel adaptation of this approach was the use of deltamethrin-impregnated collars for domestic dogs that serve as a reservoir for *L. chagasi/infantum*.<sup>268,269</sup> Residual insecticides are not useful in rural areas where wild animals serve as reservoirs and arboreal sand flies are responsible for transmission.

Reservoir control programs have also been attempted.<sup>270</sup> In northeastern and southeastern Brazil, where *L. infantum/chagasi* is endemic and domestic dogs are thought to be a major reservoir, large numbers of seropositive dogs have been killed, but the efficacy of dog eradication has not been clearly demonstrated.<sup>74,271</sup> Poisoning rodents and deep plowing have been used in Asia to reduce the reservoir density with uncertain results. In India, where humans are the reservoir of *L. donovani*, early case identification and treatment of infected patients with visceral leishmaniasis or post-kala-azar dermal leishmaniasis are potentially important elements in control.

Clinical experience in humans and studies in animals suggest that the eventual development of an effective leishmanial vaccine(s) is likely. People who have recovered from leishmaniasis develop high-level immunity against reinfection with the same *Leishmania* species. In *L. tropica* endemic areas of the Middle East, mothers have for generations exposed the bottoms of their infants to sand flies to facilitate the development of a lesion at an acceptable site and the development of immunity to protect against disfiguring lesions of the face and extremities.

In Russia and Israel, troops were “immunized” with live *L. major* promastigotes injected into the buttocks. This practice was discontinued in Israel because some of the resulting lesions were large and others healed slowly. There was also concern that parasites could persist in the skin even after clinical cure. A vaccine made of killed promastigotes from multiple strains of *Leishmania* was used in Brazil in military troops. It was shown to stimulate cellular immune responses in a subset of recipients, although its clinical efficacy in preventing cutaneous leishmaniasis was not clearly documented.<sup>272</sup>

These observations coupled with extensive studies of experimentally infected mice suggest that a defined vaccine(s) is feasible. Such a vaccine could be based on the use of recombinant antigens or possibly genetically altered, living *Leishmania* that could survive long enough in vivo to elicit protective immunity but bear mutations or gene knockouts that ultimately would result in their death. Such an *L. mexicana* strain was shown to provide protective immunity in mice.<sup>273</sup> Given the rapid advances that have been made in understanding the immunobiology of leishmaniasis, it seems that an effective vaccine will likely be developed.<sup>274,275</sup>

# Pathogenic and Opportunistic Free-Living Amebas: *Acanthamoeba* spp., *Balamuthia mandrillaris*, *Naegleria fowleri*, and *Sappinia diploidea*

GOVINDA S. VISVESVARA  
JAMES H. MAGUIRE

## INTRODUCTION

Infections caused by the pathogenic and opportunistic free-living amebas such as *Acanthamoeba*, *Balamuthia*, and *Naegleria* have been recorded from all parts of the world including the tropics.<sup>1-5</sup> Diseases caused by these amebas in tropical countries have received little attention because of more pressing health problems and the likelihood that many cases go undetected because of limited resources for diagnosis and low rates of autopsy, the method by which most infections are detected, even in industrialized countries. Because these infections occur most often in immunocompromised persons, greater numbers of cases would be expected in sub-Saharan Africa, South Asia, and other areas where the HIV epidemic is burgeoning. Limited diagnostic expertise in many developed and developing countries contributes to our lack of knowledge of the actual incidence of these infections.

## AGENTS

Pathogenic and opportunistic free-living amebas of the genera *Acanthamoeba*, *Balamuthia*, *Naegleria* are mitochondria-bearing, aerobic, eukaryotic protists. Although they exist as free-living entities in nature, they cause life- and sight-threatening

disease in humans and other animals.<sup>1-37</sup> *Acanthamoeba* and *Balamuthia* cause an insidious chronic granulomatous disease known as granulomatous amebic encephalitis (GAE) in both immunocompetent and immunosuppressed persons and animals.<sup>1-6,8-10,15,16,23-37</sup> *N. fowleri* produces a necrotizing, hemorrhagic meningoencephalitis, primary amebic meningoencephalitis (PAM), principally in healthy immunocompetent hosts who have a history of recent contact with fresh warm water.<sup>1,7,13-15,17-22,26,27</sup> Recently, *Sappinia diploidea*, a free-living ameba that normally lives in soil contaminated with feces of elk, bison, and cattle has been identified as causing encephalitis in an otherwise healthy young man.<sup>38,39</sup> Since all these amebas have the ability to exist as free-living organisms in nature and occasionally invade a host and live as parasites within host tissue, they have been called amphizoid amebas. In contrast to the free-living amebas, *Entamoeba histolytica* is an anaerobic ameba that lacks mitochondria, commonly causes gastrointestinal pathology, and is strictly parasitic.

## *Acanthamoeba* Species

Although the genus *Acanthamoeba* was named by Volkonsky in 1931, Puschkarew in 1913 first isolated the ameba from dust and named it *Ameba polyphagus*. Page later redescribed the ameba and renamed it *Acanthamoeba polyphaga*.<sup>40</sup> Sir Aldo Castellani in 1930<sup>41</sup> also isolated an ameba that occurred as a contaminant in a yeast culture plate and was later named *Acanthamoeba castellanii*. In 1958, Culbertson and colleagues demonstrated the pathogenic potential of *Acanthamoeba* when they isolated an ameba, now known as *Acanthamoeba culbertsoni*, contaminating monkey kidney cell culture during production of the poliomyelitis vaccine.<sup>42</sup> It is now well established that several species of *Acanthamoeba* (*A. castellanii*, *A. culbertsoni*, *A. healyi*, *A. polyphaga*, *A. rhysodes*) cause GAE, an insidious disease with a protracted course and usually fatal outcome.<sup>1</sup> GAE usually occurs in persons with acquired immunodeficiency syndrome (HIV/AIDS) or who are otherwise immunocompromised, debilitated, or malnourished (Fig. 95-1). In addition to GAE, *Acanthamoeba* can cause a disseminated disease involving skin, sinuses, lungs, and other organs and also a painful, sight-threatening infection of the eye, *Acanthamoeba* keratitis.<sup>1,11,12,16,43</sup>

## Life Cycle

*Acanthamoeba* has two stages in its life cycle: a feeding and reproducing trophozoite stage and a resistant cyst stage (Fig. 95-2). The trophozoites feed on bacteria and detritus present in the environment and multiply by binary fission. A unique and characteristic feature of *Acanthamoeba* is the presence of fine, tapering, thorn-like pseudopodia, acanthopodia, that emanate from its surface. The trophozoites range in size from 15 to 45  $\mu\text{m}$  and have a single nucleus with a centrally placed, large, densely staining nucleolus. The cytoplasm is finely granular and contains numerous mitochondria, ribosomes, food vacuoles, and a contractile vacuole (see Fig. 95-2A). Cysts are double walled and range in size from 10 to 25  $\mu\text{m}$ . The outer cyst wall, the ectocyst, is wrinkled with folds and ripples and contains protein and lipid. The inner cyst wall, the endocyst, contains cellulose and hence is PAS positive. It is stellate, polygonal, oval, or spherical. Pores, or ostioles, at the junction of the ectocyst and the endocyst are

FIGURE 95-1 Infections due to *Acanthamoeba* species.

covered by convex-concave opercula that open at the time of excystation. Cysts also are uninucleated and possess a centrally placed dense nucleolus (see Fig. 95-2B).<sup>40,44</sup>

### Cultivation

*Acanthamoeba* spp can be cultivated easily in the laboratory on non-nutrient agar plates coated with bacteria such as *Escherichia coli* or *Enterobacter aerogenes*. The amebas feed on the bacteria, multiply, and completely cover the surface of the plates within a few days. When almost all the bacteria have been consumed, the amebas differentiate into cysts. They can be maintained in the laboratory indefinitely by periodically cutting out a small piece of agar containing trophozoites or cysts and transplanting it onto a fresh agar plate coated with bacteria as before. Additionally, *Acanthamoeba* spp. can also be

cultured on mammalian cell cultures as well as in cell-free liquid medium.<sup>45</sup>

### *Balamuthia mandrillaris*

*B. mandrillaris*, the only known species belonging to the genus *Balamuthia*, causes GAE in both humans and other animals (Fig. 95-3). It was first isolated in 1986 from the brain tissue of a pregnant baboon from the San Diego Wild Animal Park that died of GAE. Initially described as a leptomixid ameba,<sup>25</sup> it was renamed *Balamuthia mandrillaris* in 1993.<sup>26</sup> GAE due to *B. mandrillaris* has occurred in both immunocompromised and healthy children and adults. *B. mandrillaris* is also known to cause skin infection similar to that caused by *Acanthamoeba*.

### Life Cycle

*B. mandrillaris*, like *Acanthamoeba*, has only two stages in its life cycle (Fig. 95-4). The trophozoite is pleomorphic and measures from 12 to 60  $\mu\text{m}$  with a mean of about 30  $\mu\text{m}$ . The trophozoites usually are uninucleated, but binucleate forms occasionally are seen. The nucleus contains a large, centrally placed, dense nucleolus, and occasionally trophozoites with two or three nucleolar bodies are seen, especially in infected tissues (see Fig. 95-4A). Cysts are also uninucleated, more or less spherical and range in size from 12 to 30  $\mu\text{m}$ , with a mean of 15  $\mu\text{m}$ . Under the light microscope, cysts appear to be double walled, with a wavy outer wall and a round inner wall. Ultrastructurally, however, the cysts possess three walls: an outer thin irregular ectocyst, an inner thick endocyst, and a middle amorphous fibrillar mesocyst (see Fig. 95-4B).<sup>25,26</sup>

### Cultivation

Unlike *Acanthamoeba*, *Balamuthia* cannot be cultured on agar plates coated with bacteria. Although *B. mandrillaris* has recently been isolated from the environment, its food source is not clearly known. It is believed that it feeds on other small amebas that are present in the environment. It can be grown easily in mammalian cell cultures such as monkey

FIGURE 95-2 *Acanthamoeba castellanii*: A, Trophozoite. B, Cyst. Note acanthopodia (Ap). (magnification  $\times 1000$ )

FIGURE 95-3 Infections due to *Balamuthia mandrillaris*.

kidney (E6) or human lung fibroblasts. It has also been grown axenically in cell-free medium.<sup>45,46</sup>

### *Naegleria fowleri*

*N. fowleri* causes PAM, an acute, fulminating, hemorrhagic meningoencephalitis. The infection occurs principally in healthy children and young adults with a history of recent exposure to fresh warm water and is almost always fatal within a week (Fig. 95-5). Although retrospective examination of brain tissue indicates that PAM due to *N. fowleri* occurred as far back as in 1901, it was first described in 1965 in Australia by Fowler and Carter, who attributed the

FIGURE 95-5 Primary amebic meningoencephalitis due to *Naegleria fowleri*.

infection to *Acanthamoeba*.<sup>1,17</sup> Butt described the first case of *N. fowleri* infection from the United States in 1966 and coined the term primary meningoencephalitis.<sup>18</sup>

### Life Cycle

*N. fowleri* is also called an ameboflagellate, since it has a transitory flagellate stage in addition to an ameboid trophozoite stage and a resistant cyst stage in its life cycle (Fig. 95-6). The trophozoite moves rapidly by producing hemispherical bulges, lobopodia, at the anterior end and exhibits active sinusoid locomotion. It measures 10 to 25  $\mu\text{m}$ , feeds on Gram-negative bacteria, and reproduces by binary fission. It has a single nucleus with a prominent, centrally placed nucleolus that stains densely with chromatic dyes. The cytoplasm is abundant and contains numerous mitochondria, ribosomes, food vacuoles, and a contractile vacuole (see Fig. 95-6A). The trophozoite transforms into a flagellate stage usually with two flagella when the ionic concentration of the milieu changes. The temporary flagellate stage ranges in length from 10 to 16  $\mu\text{m}$  and reverts back to the trophic stage (see Fig. 95-6B). The trophozoite transforms into the resistant cyst when the food supply diminishes and environmental conditions become adverse. The cyst is usually spherical and double walled with a thick endocyst and a closely apposed thinner ectocyst. The cyst wall has pores but may not be noticeable (see Fig. 95-6C). Both the flagellate and cyst stages possess a single nucleus with a prominent nucleolus.<sup>40,44</sup>

### Cultivation

*N. fowleri*, like *Acanthamoeba*, grows well on non-nutrient agar plates coated with bacteria. It also grows well on monolayers of E6 and HLF cells, destroying the monolayers within 2 to 3 days. Like *Acanthamoeba* and *Balamuthia*, *N. fowleri* can be grown in cell free axenic medium.<sup>45</sup>

### *Sappinia diploidea*

Gelman and colleagues<sup>38,39</sup> reported the first and only case of amebic encephalitis caused by *Sappinia diploidea* in an

immunocompetent, previously healthy 38-year-old male. The patient lost consciousness for about 45 minutes and developed nausea and vomiting followed by bifrontal headache, photophobia, and blurry vision lasting 2 to 3 days. His history was unremarkable except for a recent sinus infection. Magnetic resonance imaging (MRI) showed a solitary 2-cm mass in the posterior left temporal lobe. The excised mass on sectioning showed necrotizing hemorrhagic inflammation containing amebic organisms. The characteristic feature of the ameba was the presence of two nuclei tightly apposed to one another. Cysts were not seen. *S. diploidea* had never before implicated in human or animal disease, although it had been described as a coprozoic ameba found in feces of humans, elk, bison, and perhaps cattle. The life cycle of this ameba includes trophic and cyst stages (Fig. 95-7). Both trophozoites and cysts are binucleate, with two tightly apposed nuclei. The trophozoite measures 40 to 80  $\mu\text{m}$ , is ovoid or oblong, and appears to be flattened with occasional wrinkles on the surface. The cytoplasm contains a contractile vacuole and food vacuoles. The mature cyst is round and measures 15 to 30  $\mu\text{m}$ . *S. diploidea* can be cultivated on non-nutrient agar plate coated with bacteria.<sup>44</sup>

### Taxonomy and Classification of the Free-Living Pathogenic Amebas

Until recently, taxonomic classification was based largely on morphologic, ecologic, and physiologic criteria. Recent information derived from sequencing small subunit rRNA may change the schema of the classification of these amebas in the future. The classification of the amebas presented here is partly based on Page's taxonomic scheme.<sup>44</sup> *Acanthamoeba*, *Balamuthia*, *Naegleria*, and *Sappinia* along with a heterogeneous group of amebas that include both free-living (e.g., *Hartmannella*, *Vahlkampfia*, *Vannella*) and parasitic amebas (e.g., *Entamoeba histolytica*) belong to the phylum Rhizopoda. *Acanthamoeba* and *Balamuthia* are classified under class Lobosea, order Acanthopodida, family Acanthamoebidae. *Sappinia* is classified under class Lobosea, order Euamoebida, family Thecamoebidae. *Naegleria* is included under class Heterolobosea, order Schizopyrenida, family Vahlkampfiidae.

**FIGURE 95-7** A, CNS section of a patient with *Sappinia diploidea* infection. Note the two nuclei (N) apposed to one another. (Giemsa stain,  $\times 700$ .) B, Differential interference contrast image of a trophozoite growing in culture with bacteria. (magnification  $\times 1250$ )

## EPIDEMIOLOGY

### Ecology of Free-Living Amebas

*Acanthamoeba* species is ubiquitous and has a worldwide distribution. It has been isolated from soil, fresh and brackish water, bottled mineral water, cooling towers of electric and nuclear power plants, heating, ventilating and air conditioning units, whirlpool baths, physiotherapy pools, dialysis machines, dust in the air, bacterial, fungal and mammalian cell cultures, contact lens paraphernalia, and the nose and throat of healthy persons and persons with respiratory complaints.<sup>1,2,11,12,15,16,26,27,41–43,47–49</sup> It has also been isolated from brain, lungs, skin, and cornea of infected individuals. Cases of *Acanthamoeba* GAE may occur at any time of the year without relation to seasonality.<sup>1</sup> *Acanthamoeba* spp harbor pathogenic microorganisms such as *Legionella* spp., *Mycobacteria*, *Francisella tularensis*, *E. coli* 0571, and *Burkholderia* and thus may be of greater public health importance than previously believed.<sup>50–52</sup>

The environmental niche of *B. mandrillaris* was not known until recently, because it had been isolated only from biopsy and autopsy specimens of humans and other animals. Schuster and associates in 2003<sup>53</sup> reported the isolation of *B. mandrillaris* from the soil of a flowerpot in the household of a person in California who died of GAE. Cases of *Balamuthia* GAE also occur at any time of the year without relation to seasonal changes.<sup>1,9</sup>

*N. fowleri* is widely distributed throughout the world and has been isolated from fresh water, thermal discharges of power plants, heated swimming pools, hot springs, hydrotherapy and remedial pools, aquaria, sewage, and even the nasal passages and throats of healthy individuals.<sup>1,13,15,19–22,47–49</sup> Typically, cases of PAM occur in the hot summer months when large numbers of people engage in aquatic activities in lakes, ponds, swimming pools, and other warm, fresh water bodies that may harbor these amebas.<sup>1</sup>

*Sappinia diploidea* has been isolated from soil, fresh water, forest litter, mammalian feces, and the rectum of lizards. It has been described from Europe, North America, Egypt, Middle East, the West Indies, and Japan.<sup>38,39,44</sup>

## DISEASES

### Granulomatous Amebic Encephalitis

The clinical manifestations of patients infected with either *Acanthamoeba* spp or *B. mandrillaris* are similar and will be considered together. The incubation period is unknown, although in disseminated infections, several weeks or months may elapse between the appearance of cutaneous lesions and the recognition of central nervous system (CNS) disease.<sup>54,55</sup> Neurologic symptoms develop insidiously, and most patients have focal deficits or alteration in mental status. There may be headache, meningismus, nausea, vomiting, lethargy, or low-grade fever. Localizing signs include seizures, hemiparesis, visual disturbances, facial nerve palsy, ataxia, and other cerebellar signs. Over the course of a week to several months, the disease progresses to coma and eventually death from increased intracranial pressure and brain herniation or from secondary infection and multiorgan failure. Initially, MRI shows one or a few lesions, even when computerized tomography (CT) scans of the brain are unremarkable. Lesions typically are of low density with peripheral ring enhancement and mass effect.<sup>56,57</sup> Over time, lesions increase in size and number to involve the cerebral hemispheres, cerebellum, brainstem, and thalamus. CT and MRI may indicate hemorrhage within lesions, and angiography may demonstrate occluded blood vessels corresponding to areas of infarction. Examination of cerebrospinal fluid (CSF) shows a predominantly lymphocytic pleocytosis typically with less than 500 cells/mm<sup>3</sup>, increased protein, and decreased or normal glucose.

In GAE, there frequently is evidence of infection in the skin, and in cases due to *Acanthamoeba* spp., the lungs or sinuses may be affected as well; any of these sites may be the primary focus of infection that leads to hematogenous dissemination. In the skin, initially minor lesions develop into firm nodules, nonhealing ulcers, and subcutaneous abscesses, mostly on the chest and limbs (Fig. 95-8). Cutaneous involvement can occur with or without involvement of the CNS.<sup>1,16,24–27</sup> Radiographs of the lungs may show focal areas of pneumonitis and consolidation. Chronic sinusitis has been reported in *Acanthamoeba* infections primarily in persons with

**FIGURE 95-8** A, HIV/AIDS patient with skin ulcers caused by *Acanthamoeba*. B, A section through the ulcer showing *Acanthamoeba* trophozoites (T) and cysts (C). (H&E stain,  $\times 1000$ )

AIDS, and there have been reports of osteomyelitis, otitis, endophthalmitis, and adrenalitis in immunosuppressed patients with and without AIDS. There are reports of identification of *Acanthamoeba* spp or *B. mandrillaris* in other organs, such as kidneys, lymph nodes, liver, prostate, testes, and uterus.

### Pathologic Findings

The initial site of infection in GAE, due to either *Acanthamoeba* or *Balamuthia*, probably is the lower respiratory tract, skin, or sinuses, and invasion of the brain and other organs results from hematogenous spread from these sites. On gross examination, the brain is edematous and there may be evidence of uncal and tonsillar herniation. Multiple areas of meningeal softening and inflammation overlie necrotic and hemorrhagic lesions in the cortex (Figs. 95-9 and 95-10). Such lesions extend into the white matter in the brainstem, cerebral hemispheres, and cerebellum and have the appearance of hemorrhagic infarcts. Microscopic examination shows amebic trophozoites and cysts in necrotic and viable tissue within the CNS, skin, lungs, and other organs (see Fig. 95-9B). There are areas of necrosis, hemorrhage, and inflammatory infiltrates, consisting of neutrophils, mononuclear cells, and multinucleated giant cells. Trophozoites and cysts of *Acanthamoeba* are seen extracellularly or within macrophages, which also contain lipid (see Fig. 95-9B). In the case of *Balamuthia* infection, the nucleus of the trophozoites may occasionally contain two or three nucleoli (see Fig. 95-10B).

The walls of blood vessels are surrounded and infiltrated with amebas, which may provoke vasculitis and thrombosis.<sup>1,6,9,23-37</sup> In some patients, especially those with advanced HIV disease, the inflammatory reaction is sparse and granulomas are not present.

### Pathogenesis and Immunity

With a few exceptions, GAE caused by *Acanthamoeba* spp affects hosts whose metabolic, physiologic, or immunologic integrity are lost, whereas disease due to *Balamuthia* affects both healthy and immunocompromised persons. Among the commonly recognized causes of susceptibility to these infections are diseases or conditions such as AIDS, hematologic malignancies, cancer, liver disease, diabetes mellitus, pregnancy, and therapy with corticosteroids and other immunosuppressive drugs following organ transplantation.<sup>1</sup> The etiologic agents may enter the skin or reach the respiratory tract through aerosol or inhalation of airborne dust containing the trophic or cyst stage. The trophozoites or most likely the cysts may temporarily be contained at the site of entry by the body's immune system. However, if the immune system is impaired, or in healthy persons, for reasons not well understood, the cyst excysts and trophozoites invade tissue and gain access to the circulation, where they are carried to the brain and other organs. In an immunocompetent host, immunoglobulins and complement promote recognition of these amebas by neutrophils, macrophages, and lymphocytes. These cells,

**FIGURE 95-9** Brain section of a patient infected with *Acanthamoeba* (H&E stain). A, Low-power view of a CNS section showing chronic inflammatory changes. (magnification  $\times 100$ ) B, Higher magnification ( $\times 1000$ ) showing the characteristic nuclear morphology of the trophozoite cysts (C) with double walls.

**FIGURE 95-10** CNS section of a patient that died of *Balamuthia mandrillaris* GAE (H&E stain). A, Low-power view depicting intense inflammatory reaction. (magnification  $\times 100$ ) B, Higher magnification ( $\times 1000$ ) of the same section showing a trophozoite with multiple nucleoli (N) and cysts (C).

through the cytokines, destroy the amebas. However, in susceptible persons these elements are absent or impaired, and amebas continue to proliferate and damage host tissues.

Since *Acanthamoeba* and other small amebas are ubiquitous in nature it is reasonable to expect humans and other animals to be exposed to the amebas or their antigens and develop serum antibodies to them. Whether this natural antibody results in the development of protective immunity against infection is not known. Previous studies have shown that antibodies to *Acanthamoeba* exist in sera of healthy soldiers as well as hospitalized patients in Czechoslovakia, adults and children from New Zealand, and patients hospitalized for respiratory disorders.<sup>1,15,16,58–60</sup> Antibodies to *Acanthamoeba* have also been demonstrated in patients who developed GAE.<sup>1,4,35,37</sup> For example, a Nigerian patient from whose CSF *A. rhysodes* was repeatedly isolated exhibited an increase in titer from 256 to 1024 against *A. rhysodes* in serum samples collected 16 months apart.<sup>4</sup> Antibody titer for *A. castellanii* of 512 was detected in an immunocompromised patient with systemic lupus erythematosus who developed *Acanthamoeba* encephalitis.<sup>37</sup> High titers (256) of antibody to *A. castellanii* were also demonstrated in an acute serum sample from a renal transplant patient with cutaneous acanthamebiasis who had been taking immunosuppressive medications.<sup>37</sup> It is interesting to note that complement-fixing antibody to *A. culbertsoni* was demonstrated in 2 of 1000 serum samples collected randomly in the United States. Notably, one of the serum samples was from a patient with an old brain infarct. The initial serum sample had a complement fixation titer of 8 that rose to 16 and 64 in subsequent serum samples taken 1 and 2 months, respectively, after the initial sample was collected.<sup>1,15</sup> The patient subsequently died of cerebral hemorrhage, and amebas were demonstrated in the brain sections. Of note, in vitro studies have demonstrated that *Acanthamoeba* activates the alternative complement pathway, which is independent of antibody activation.<sup>1,15,16,56</sup>

Antibodies to *B. mandrillaris* have been demonstrated in sera from healthy individuals in South Australia using immunofluorescence and flow cytometry. Antibodies of the IgG and

IgM classes were detected with titers ranging from 64 to 256.<sup>61</sup> In another study, about 3% of approximately 225 serum samples collected from patients hospitalized with encephalitis in California had titers of about 128 for anti-*B. mandrillaris* antibody by immunofluorescence testing.<sup>62</sup> All these patients were confirmed as having been infected with *B. mandrillaris* by specific immunostaining of biopsy sections using rabbit anti-*B. mandrillaris* serum. Two patients that survived the infection had anti-*B. mandrillaris* titers of 128 in the acute phase that decreased to 64 during convalescence.<sup>30</sup>

### *Acanthamoeba* Keratitis

*Acanthamoeba* keratitis (AK) is a painful, sight-threatening infection of the cornea that may lead to chronic ulceration of the cornea, loss of visual acuity, and eventually blindness and enucleation (Fig. 95-11). AK generally affects healthy persons and is associated with trauma to the cornea or minor erosion of the corneal epithelium from hard or soft contact lens wear and the subsequent use of contaminated saline solution. It is characterized by corneal inflammation, severe ocular pain, photophobia, tearing, blurred vision, and refractoriness to the commonly used antibiotics and antifungal and antiviral agents. Amebas adhere to corneal epithelial cells and secrete proteinases that facilitate invasion of the cornea and later the underlying stroma.<sup>63</sup> Amebic trophozoites and cysts are seen between the lamellae of the cornea, and inflammatory infiltrates consisting primarily of polymorphonuclear leukocytes in the superficial and middle layers of the corneal stroma are common (see Fig. 95-11B). Infiltration of nerves causes radial keratoneuritis, and later a characteristic 360° or paracentral stromal ring infiltrate develops. Anterior uveitis is common. In late stages, AK is characterized by necrosis, ulceration, descemetocoele formation, and perforation of the cornea. A nonsuppurative keratitis with recurrent ulceration and a waxing and waning clinical course is a typical history. AK is often misdiagnosed as dendritic keratitis due to herpes simplex virus.<sup>1,11,12,15,16</sup>

**FIGURE 95-11** *Acanthamoeba* keratitis. Note the concentric ring infiltrate (A) and a section of the cornea showing *Acanthamoeba* trophozoite in the corneal stroma (B). (magnification  $\times 1000$ )

Immunoblotting was used to test sera from normal individuals and keratitis patients for anti-*Acanthamoeba* antibodies and immune reactivity. Significantly, sera from keratitis patients had low levels of IgA, perhaps indicative of a greater vulnerability to AK.<sup>1,16,60,64</sup> In another study, immunofluorescent and precipitin antibody to *Acanthamoeba* were demonstrated in patients with *Acanthamoeba* keratitis.<sup>1,11,12,15,16,60</sup>

### Primary Amebic Meningoencephalitis

PAM is an acute, fulminating, rapidly fatal disease that usually affects children and young adults with a history of recent contact with warm fresh water. The time from fresh water contact (swimming and diving, water skiing, or simply immersing the head in water) to onset of illness is typically 5 to 7 days. The cause of death usually is increased intracranial pressure with brain herniation leading to cardiopulmonary arrest and pulmonary edema. Early in the illness, patients may experience changes in smell or taste, but usually the first symptoms are sudden onset of bifrontal or bitemporal headaches, high fever, neck stiffness, nausea, and vomiting. Irritability, restlessness, and mental status changes are present at initial presentation, and nuchal rigidity and positive Kernig's and Brudzinski's signs can be demonstrated. Photophobia may occur late in the clinical course followed by neurologic abnormalities including lethargy, seizures, confusion, coma, diplopia, or bizarre behavior. Cranial nerve palsies (third, fourth, and sixth cranial nerves) may indicate brain herniation from brain edema and increased intracranial pressure, often in excess of 600 mm H<sub>2</sub>O. Death occurs within a week of onset of symptoms. Cardiac rhythm abnormalities and myocardial necrosis are sometimes found. CT scan of the head without contrast is often normal or shows cerebral edema with obliteration of the cisterns surrounding the midbrain and the subarachnoid space over the cerebral hemispheres. Marked diffuse enhancement in these regions may be seen after administration of intravenous contrast medium.<sup>56</sup> CSF may vary in color from grayish to yellowish-white, tinged red with as few as 250/mm<sup>3</sup> red cells in the early stages. However, as the disease progresses the red blood cells increase in number to as high as 24,600/mm<sup>3</sup>. CSF white

blood cells, predominantly polymorphonuclear leukocytes, vary from 300 mm<sup>3</sup> to as high as 26,000 mm<sup>3</sup>. CSF protein may reach 580 mg/mL or higher, and glucose levels of 10 mg/100 mL or lower are commonly seen.<sup>1,13-15,17-22,27</sup>

### Pathologic Findings

The cerebral hemispheres are usually soft, markedly swollen, edematous, and severely congested. Uncal and tonsillar herniations are present. The leptomeninges are severely congested, diffusely hyperemic, and opaque, with limited purulent exudate within sulci, at the base of the brain, and around the brainstem and cerebellum. The olfactory bulbs are markedly hemorrhagic and necrotic and are usually surrounded by purulent exudate. The cortex shows numerous superficial hemorrhagic areas, most commonly in the base of the orbitofrontal and temporal lobes, base of the brain, hypothalamus, midbrain, pons, medulla oblongata, and upper portion of the spinal cord.<sup>1,27</sup>

Microscopically, the cerebral hemispheres, brainstem, cerebellum, and upper portion of the spinal cord are suffused with fibrinopurulent leptomeningeal exudate containing numerous neutrophils, some lymphocytes, and few eosinophils and macrophages. Large numbers of trophozoites, usually in pockets and without the presence of neutrophils, are seen within edematous and necrotic neural tissue (Fig. 95-12). Trophozoites also are abundant deep in Virchow-Robin spaces, usually around blood vessels, but with no inflammatory response. Amebas ranging in size from 8 to 12  $\mu$ m are characterized by the presence of a large nucleus with a centrally located, deeply staining large nucleolus. Amebic cysts are conspicuously absent.<sup>1,17,18,27</sup>

### Pathogenesis and Immunity

The portal of entry into the CNS is the olfactory neuroepithelium. It is believed that the sustentacular cells lining the olfactory neuroepithelium phagocytose the amebas that enter the nasal passages of the victims while indulging in aquatic activities. The amebic trophozoites penetrate the cribriform

**FIGURE 95-12** A, CNS section of a patient who died of primary amebic meningoencephalitis due to *Naegleria fowleri*. (H&E stain,  $\times 100$ ) B, Higher magnification ( $\times 1000$ ) showing numerous amebic trophozoites but no cysts.

plate of the ethmoid bone, enter the subarachnoid space, and eventually reach the brain parenchyma. *N. fowleri* trophozoites likely possess virulence factors that contribute to the dissolution and necrosis of brain tissue, such as production and secretion of a phospholipase, release of neuraminidase, creation of pores in target cell membranes, and aggressive phagocytic activity. Additionally, amebas possess amebostomes, or food cups, that are capable of pinching off bits and pieces of brain cell cytoplasm.<sup>1,27</sup>

The incubation period of PAM, which varies from 2 to 15 days, depends on the size of the inoculum and the virulence of the amebas. The importance of virulence is illustrated by incubation periods as long as 3 or 4 weeks in experimental infections that employed a mildly virulent strain of *N. fowleri*.<sup>1</sup>

Very little information exists on the antibody response to *N. fowleri* infection, probably because most patients die before serum antibodies become detectable. However, in one patient who survived PAM infection, an antibody titer of 4096 to *N. fowleri* was demonstrated by immunofluorescence in serum samples obtained at 7, 10, and 42 days of hospitalization; antibodies to *N. fowleri* were still present after 4 years.<sup>20</sup> There are reports of antibodies to *N. fowleri* and other *Naegleria* species in serum samples of hospitalized patients in Tennessee as well as in apparently healthy persons.<sup>1,15,27,65,66</sup> IgG but not IgM antibodies were detected in sera from newborn infants, indicating transplacental transfer.<sup>62</sup> A difference was noted in the capacity of sera from Pennsylvania residents to agglutinate *N. fowleri* and other *Naegleria* spp. when compared with sera obtained from residents of North Carolina. Sera from the southeastern area had significantly greater agglutinating ability (attributable to IgM antibodies) than those of the northeastern state, suggesting a higher degree of exposure to *N. fowleri* in persons from the warmer southern region.<sup>66</sup> Apparently, normal human serum, but not heat-inactivated serum, stimulates production of protein kinases in *N. fowleri*, which may be effective in destroying complement and protecting amebas from the membrane-attack complex of the complement cascade.<sup>67</sup>

## DIAGNOSIS: CLINICAL AND LABORATORY METHODS

### Granulomatous Amebic Encephalitis

#### Neuroimaging

CT and MRI scans of the head demonstrate the presence of single or multiple lesions but are not specific for GAE. The typical enhancing, space-occupying lesions of *Acanthamoeba* or *Balamuthia* infection can mimic brain abscess, tumor, cerebrovascular accidents, and other diseases.<sup>1</sup>

#### CSF Examination

Lumbar puncture is often contraindicated in patients with GAE and large or multiple lesions because of the risk of herniation. When CSF is obtained, analysis usually shows lymphocytic pleocytosis with mild elevation of proteins and normal glucose, but no amebas. Unlike *N. fowleri*, *Acanthamoeba* spp and *B. mandrillaris* are not readily found in the CSF. There have been only a few reports of isolation of *Acanthamoeba* spp.; in one case it was isolated repeatedly from the CSF of a Nigerian patient.

#### Brain and Skin Biopsies

Although in many cases of GAE the diagnosis was made only at autopsy, brain and skin biopsies have yielded *Acanthamoeba* spp. and *B. mandrillaris* in specimens from several patients antemortem.<sup>1,8,15,30,31,33,34</sup> Biopsies in a few patients were lifesaving because they permitted timely administration of specific therapy.<sup>1,5,9,16,24,30,31,33,34</sup> In general, *Acanthamoeba* spp. and *B. mandrillaris* are difficult to differentiate in tissue sections by light microscopy because of their similar morphology although occasionally it may be possible to identify *Balamuthia* based on the presence of multiple nucleoli within the nucleus (see Fig. 95-10B).<sup>1,3,9,16,24-28,32</sup> However, they can be differentiated by immunofluorescence

analysis of tissue sections using rabbit anti-*Acanthamoeba* or anti-*B. mandrillaris* sera. Biopsy or autopsy tissues fixed in formalin can be deparaffinized, rehydrated, post-fixed in Karnovsky's, dehydrated, and embedded in plastic (EPON) for electron microscopic studies. Ultrastructural examination demonstrates the characteristic features of trophozoites and cysts and facilitates the identification of the specific ameba. For identification of the species of *Acanthamoeba*, it is necessary to perform immunohistochemistry (either immunoperoxidase or immunofluorescence test) on tissue specimens or amebas in culture. Unlike *Acanthamoeba* spp., *Balamuthia* cannot be easily cultured on non-nutrient agar plates seeded with bacteria. Hence biopsy specimens should be inoculated on layers of mammalian cell cultures.<sup>24,25</sup> Specimens for culture should be processed as soon as possible.<sup>1,15,24</sup>

PCR has been used widely as a means of improving on the taxonomy and understanding the phylogeny of members of the genus *Acanthamoeba* and in identification of amebas in culture.<sup>12,68</sup> A PCR probe consisting of a primer pair specific for *Balamuthia* has been developed from sequence data of mitochondrial 16S rRNA genes.<sup>69</sup> Using this specific probe a clinical isolate obtained from the brain of a child was found to be identical to an ameba isolated from flowerpot soil in the home of the child.<sup>70</sup> Hopefully such precise tests will become common in the future.

### ***Acanthamoeba* Keratitis**

#### **Clinical and Laboratory Diagnostic Methods**

Ocular infections with *Acanthamoeba* can resemble bacterial, fungal, or viral infections, especially those caused by herpes simplex virus. A history of corneal trauma or use of potentially contaminated contact lens solution, the characteristic ring infiltrates, and failure of conventional antimicrobial agents should suggest the diagnosis.

Trophozoites and especially cysts can be recovered from corneal scrapings or biopsy specimens but not from swabs. When microscopic examination or culture of specimens is negative, culturing amebas from contact lenses, lens case, or cleaning solution lend support to a clinical diagnosis of AK. Molecular techniques are employed increasingly in the identification of the ameba in samples of corneal epithelium and tear fluid and in the identification of the genotype of *Acanthamoeba*.<sup>1,12,16,71,72</sup> Scanning confocal microscopy allows in vivo visualization of cysts and trophozoites in the cornea.<sup>73</sup>

### **Primary Amebic Meningoencephalitis**

No distinctive clinical features differentiate PAM from acute bacterial meningitis or meningoencephalitis although failure of broad-spectrum antibiotics may alert the clinician to the possibility of a nonbacterial cause of the rapidly progressive illness. It is crucial to obtain a history of potential exposure to warm fresh water or hot springs during the past week.

#### **CSF Examination**

The CSF pressure is usually elevated (300 to >600 mm H<sub>2</sub>O). The cerebrospinal fluid is characterized by a neutrophil-predominant pleocytosis, absence of bacteria, normal or

decreased glucose concentration, and elevated protein content in the range of 100 mg/100 mL to 1000 mg/100 mL. A wet mount of the CSF should be examined immediately under the microscope for the presence of actively moving trophozoites. Smears of CSF should be stained with Giemsa or Wright stain to identify the trophozoite by delineating the nucleus with a centrally placed, large nucleolus. Gram's stain is not useful.

#### **Neuroimaging Findings**

CT scans of the head are usually done without contrast in the evaluation of cases of meningitis, and in PAM, the findings are unremarkable or show only cerebral edema. When contrast is administered, meningeal enhancement of the basilar cisterns and sulci may be seen, but these are not specific for amebic infection.<sup>1,56</sup>

Serologic tests usually are of no value in the diagnosis of *N. fowleri* infections, since most patients die too soon (within 5–7 days) in the disease process to mount a detectable immune response.

Molecular techniques such as PCR and nested PCR assays for the specific identification of *N. fowleri* in cultured amebas from patients and the environment as well as *N. fowleri* DNA in the environment have been developed.<sup>74–76</sup> Sequencing of the 5.8S rRNA gene and the internal transcribed spacers 1 and 2 (ITS1 and ITS2) of *N. fowleri* has shown that the genomic region can be used to identify specific genotypes. Epidemiologic typing of *N. fowleri* has also been done by analyzing the 5.8S rRNA gene and the ITS of clinical isolates.<sup>74–76</sup> For example, *N. fowleri* amebas isolated from two cases who had visited the same hot spring in California at different times belonged to the same genotype (II), and these in turn differed from genotypes of other *N. fowleri* strains examined.<sup>63,65</sup> Although such precise tests have not been used as yet to identify *N. fowleri* DNA in CSF or brain tissue, research is on the horizon and soon there will be PCR-based assays to identify *N. fowleri*-specific DNA in the CSF.

## **TREATMENT AND PROGNOSIS**

### **Granulomatous Amebic Encephalitis**

Because most cases of GAE have been diagnosed post-mortem or only a few days pre-mortem, experience with specific treatment is limited, and current recommendations are based on in vitro studies of susceptibility of isolates to different antimicrobial agents and a small number of cases of successful treatment. Treatment is more likely to succeed if the diagnosis is made early in the course of the disease and treatment is instituted before the infection disseminates, particularly to the CNS. Several patients with GAE due to *Acanthamoeba* and *Acanthamoeba* cutaneous infection without CNS involvement have been successfully treated with multidrug regimens consisting of various combinations of pentamidine isethionate, sulfadiazine, 5' flucytosine, fluconazole or itraconazole, trimethoprim-sulfamethoxazole, and topical application of chlorhexidine gluconate for skin ulcers.<sup>1,5,16,26,33–35</sup> In vitro experiments suggests that azithromycin may also be of value in the treatment of *Acanthamoeba* GAE. Cure of infection in a few cases with involvement of the nasal mucosa

and paranasal sinuses has included surgical debridement of diseased tissue. Three patients with GAE caused by *B. mandrillaris* also have recovered from the disease. They were treated with pentamidine isethionate, sulfadiazine, azithromycin or clarithromycin, fluconazole, and in two cases flucytosine as well.<sup>9,30,31</sup>

### ***Acanthamoeba* Keratitis**

Unlike GAE, AK often can be cured by aggressive application of topical antimicrobial agents that achieve high tissue levels, and surgery when necessary. In early infections, debridement may remove infectious organisms or improve the penetration of antimicrobial drugs. Medical cure has been achieved with the application of either polyhexamethylene biguanide (PHMB) or chlorhexidine gluconate with or without propamidine isethionate (Brolene). When medical treatment failed, a combination of debridement and penetrating keratoplasty has been used with good results in some cases.<sup>1,11,12,16</sup>

### **Primary Amebic Meningoencephalitis**

PAM is almost always fatal. Only a few patients have survived this disease. A well-studied patient, a California girl, who survived the infection was aggressively treated with intravenous and intrathecal amphotericin B, intravenous and intrathecal miconazole, and oral rifampin. At 4 years' follow-up, she was found to be completely healthy and free of neurologic deficits.<sup>20</sup> In vitro studies clearly indicate that amphotericin B is greater than 10 times as active as miconazole. Miconazole is not available in the United States.

## **PREVENTION AND CONTROL**

### **Granulomatous Amebic Encephalitis**

Diseases produced by *A. castellanii* spp. and by *B. mandrillaris* have occurred most often in hosts with weakened immune systems, and presently no clearly defined methods are available for the prevention of infection with these amoebas.

### ***Acanthamoeba* Keratitis**

Contact lenses, which are being used not only for vision correction but also for cosmetic purposes, are the major risk factor for AK along with use of contaminated lens solutions. Education of patients regarding the proper care of contact lenses is important in the prevention of AK. Contact lenses should not be used during swimming or while performing water-sport activities.

### **Primary Amebic Meningoencephalitis**

*N. fowleri* is a thermophilic amoeba and hence it proliferates when the ambient temperature increases (above 30°C). As global temperature increases because of global warming, cases of *N. fowleri* PAM may be seen in countries where it has not been recorded. Since *N. fowleri* is susceptible to chlorine at one part per million, it can be controlled readily by adequate chlorination of swimming pools, including during

warm summer months. However, it is not possible to chlorinate natural bodies of water such as lakes and ponds, where *N. fowleri* may proliferate. Appropriate warnings should therefore be posted around such areas, particularly during the hot summer months.

# Microsporidiosis

LOUIS M. WEISS  
DAVID A. SCHWARTZ

## INTRODUCTION

Early on in the development of the field of microbiology, the Microsporidia were identified as the infectious pathogen responsible for pebrine, a disease of the economically important silkworm.<sup>1</sup> The Microsporidia are worldwide in distribution, with infections reported from all continents except Antarctica.<sup>2-10</sup> They are obligate intracellular eukaryotic parasites. As is true for many pathogens, the frequency of infection may be higher in tropical countries, as suggested by early serologic studies of travelers and residents of the tropics.<sup>11,12</sup> These organisms are most likely zoonotic and/or water-borne infections. The Microsporidia infect nearly every animal phyla including other protists. They are important veterinary and agricultural parasites in insects, fish, birds, laboratory rodents, rabbits, dogs, primates, and many other mammals.<sup>13</sup> Microsporidia have also been described in many animals kept as household pets.<sup>13,14</sup> Some species of Microsporidia have been used as biologic pesticides for the biologic control of destructive species of grasshoppers and locusts.<sup>15</sup> Microsporidia were first recognized in mammalian tissue more than 75 years ago<sup>16</sup> and suspected as being etiologic in human disease in 1959<sup>17</sup> in a child with encephalitis.

## AGENTS

The class or order Microsporidia was elevated to the phylum Microspora in 1977 by Sprague and Vavra.<sup>18</sup> Sprague and Becnel suggested that the term Microsporidia should be used instead for the phylum; as such, the term "Microsporidia" is a proper name and should be capitalized.<sup>19</sup> Although traditionally believed to be "primitive" protozoa, recent molecular phylogenetic analysis has suggested that Microsporidia are related to the fungi.<sup>20-22</sup> Microsporidia are currently classified on the basis of ultrastructural features, including size and morphology of the spores, number of coils of the polar tube, developmental life cycle, and host-parasite relationship. Tuzet and colleagues,<sup>23</sup> Sprague and Vavra,<sup>18</sup> Larsson,<sup>24</sup> Issi,<sup>25</sup> Weiser,<sup>26</sup> and Sprague and associates<sup>27</sup> provide overviews of the history, ultrastructural and structural characteristics, and life cycle differences among taxa of Microsporidia. Sequence data of rRNA from the Microsporidia have been used to develop diagnostic polymerase chain reaction (PCR) primers and in the study of phylogenetic relationships (reviewed in Weiss and Vossbrinck<sup>28</sup>).

The phylum Microsporidia contains more than 1000 species distributed into 144 genera, of which the following have been demonstrated in human disease (Table 96-1)<sup>13,27</sup>:

*Nosema* (*N. corneum* renamed *Vittaforma corneae*<sup>29</sup> and *N. algerae* renamed *Bracheola algerae*<sup>30</sup>), *Pleistophora*, *Encephalitozoon*, *Enterocytozoon*,<sup>31</sup> *Septata*<sup>32</sup> (reclassified as *Encephalitozoon*<sup>33</sup>), *Trachipleistophora*,<sup>34,35</sup> *Brachiola*,<sup>30</sup> and *Microsporidium*.<sup>13</sup> Within their hosts, Microsporidia often infect the digestive tract, but reproductive, respiratory, muscle, excretory, and nervous system infections also occur.<sup>13,36</sup> In the immunosuppressed host (e.g., those treated with immunosuppressive drugs or those infected with human immunodeficiency virus [HIV]), microsporidian infection can produce a wide range of clinical diseases. Reports of diarrheal syndromes in patients with acquired immunodeficiency syndrome (AIDS) due to microsporidiosis were first published in 1985.<sup>31</sup> In addition to gastrointestinal tract involvement, it has been recognized that Microsporidia can infect virtually any organ system, and cases of encephalitis, ocular infection, sinusitis, myositis, and disseminated infection are well described in the literature. These organisms have also been reported in immune-competent individuals. Other intestinal pathogens may occur simultaneously or sequentially with microsporidiosis.<sup>37</sup>

**Table 96-1 Microsporidia Identified as Pathogenic to Humans**

Genus (Species)	Reported Infections
<i>Encephalitozoon</i>	
<i>Enc. cuniculi</i>	Hepatitis, peritonitis, nephritis, encephalitis, <sup>†</sup> urethritis, cellulitis, prostatitis, sinusitis, keratoconjunctivitis, cystitis, diarrhea, <sup>†</sup> disseminated infection
<i>Enc. hellem</i> *	Keratoconjunctivitis, sinusitis, prostatitis, pneumonitis, nephritis, urethritis, cystitis, diarrhea, disseminated infection
<i>Enc. intestinalis</i> *	Diarrhea, <sup>†</sup> intestinal perforation, keratoconjunctivitis, cholangitis, nephritis
<i>Enterocytozoon bienersi</i>	Diarrhea, <sup>†</sup> wasting syndrome, cholangitis, rhinitis, bronchitis
<i>Trachipleistophora</i>	
<i>T. hominis</i> *	Myositis, keratoconjunctivitis, sinusitis
<i>T. anthropoptera</i>	Encephalitis, disseminated infection
<i>Pleistophora</i> sp.	
<i>P. ronneafiei</i>	Myositis
<i>Pleistophora</i> sp.	Myositis <sup>†</sup>
<i>Brachiola</i>	
<i>B. vesicularam</i>	Myositis
<i>B. (Nosema) algerae</i> *	Keratoconjunctivitis, myositis, skin infection
<i>B. (Nosema) connori</i>	Disseminated infection
<i>Nosema</i>	
<i>N. oculorum</i>	Keratoconjunctivitis <sup>†</sup>
<i>Vittaforma</i>	
<i>Vittaforma corneae</i> *	Keratoconjunctivitis, <sup>†</sup> urinary tract infection
<i>Microsporidium</i>	
<i>Microsporidium africanus</i>	Corneal ulcer <sup>†</sup>
<i>Microsporidium ceylonensis</i>	Corneal ulcer <sup>†</sup>

\*Organism can be grown in tissue culture.

<sup>†</sup>Cases reported in immunocompetent hosts.

The Microsporidia are eukaryotes containing a nucleus with a nuclear envelope, an intracytoplasmic membrane system, and chromosome separation on mitotic spindles, as well as vesicular golgi<sup>38</sup> and a mitochondrial “remnant.”<sup>39</sup> The genome size of the Microsporidia varies from 2.3 to 19.5 Mb,<sup>40</sup> with that of the Encephalitozoonidae being less than 3.0 Mb (making these among the smallest eukaryotic genomes so far identified).<sup>41</sup> Chromosomal analysis of *Encephalitozoon cuniculi* suggests it is diploid.<sup>42</sup> The Microsporidia form characteristic unicellular spores (Figs. 96-1 and 96-2) that, for the human pathogenic microsporidia, range from 1.0 to 3.0  $\mu\text{m}$  by 1.5 to 4.0  $\mu\text{m}$  in size.<sup>13,43</sup> The spore coat consists of an electron-dense, proteinaceous exospore, an electron-lucent endospore composed of chitin and protein, and an inner membrane or plasmalemma.<sup>44</sup> A defining characteristic of all Microsporidia is an extrusion apparatus consisting of a polar tube that is attached to the inside of the anterior end of the spore by an anchoring disc and coils around the sporoplasm in the spore (Fig. 96-3). During germination, the polar tube rapidly everts forming a hollow tube that brings the sporoplasm into

**FIGURE 96-1** Structure of a microsporidian spore. Depending on the species, the size of the spore can vary from 1 to 10  $\mu\text{m}$ , and the number of polar tubule coils can vary from a few to 30 or more. The extrusion apparatus consists of the polar tube (PT), vesiculotubular polaroplast (VPI), lamellar polaroplast (PI), the anchoring disc (AD), and manubrium (M). This organelle is characteristic of the microsporidia. A cross-section of the coiled polar tube is illustrated. The nucleus (Nu) may be single (such as in encephalitozoonae and enterocytozoonae) or a pair of abutted nuclei termed a *diplokaryon* (such as in *Nosema*). The endospore (En) is an inner, thicker, electron-lucent region, and the exospore (Ex) is an outer electron-dense region. The plasma membrane (Pm) separates the spore coat from the sporoplasm (Sp), which contains ribosomes in a coiled helical array. The posterior vacuole (PV) is a membrane-bound structure. (From Wittner M, Weiss LM [eds]: The Microsporidia and Microsporidiosis. Washington, DC, ASM Press, 1999.)

**FIGURE 96-2** Transmission electron microscopy of mature spores of *Encephalitozoon hellem* in a parasitophorous vacuole. The spore wall consists of an electron-dense exospore (open arrows) and an electron-lucent endospore (large solid arrows). The characteristic coiled polar tube, also known as the polar filament, is seen in cross-section (arrowheads). One can also see the polaroplasts (p) within the sporoplasm (s) as well as ribosomes and rough endoplasmic reticulum. Some extruded polar tubules are seen in cross-section (small arrows), and empty spores (e) are also seen that have discharged their contents. (Original magnification  $\times 7000$ .)

**FIGURE 96-3** Scanning electron microscopy of a single mature spore of *Encephalitozoon hellem* from tissue culture demonstrating an extruded polar tube. (Original magnification  $\times 8000$ .) (From Schwartz DA, Sokotka I, Leitch GJ, et al: Pathology of microsporidiosis. Emerging parasitic infections in patients with the acquired immunodeficiency syndrome. Arch Pathol Lab Med 120:173–188, 1996.)

intimate contact with the host cell. The polar tube provides a bridge to deliver the sporoplasm to the host cell. The mechanism by which the polar tube interacts with the host cell membrane is not known, but this may require the participation of the host cell.<sup>45</sup> If a spore is phagocytosed by a host cell,

germination will occur and the polar tube can pierce the phagocytic vacuole, delivering the sporoplasm into the host cell cytoplasm. The overall process of germination and formation of the polar tube inoculates the sporoplasm directly into a host cell, functioning essentially like a hypodermic needle.<sup>46,47</sup>

The general features of the microsporidian life cycle are as follows:

1. Spores are ingested or inhaled and then germinate, resulting in the extension of the polar tube, which injects the sporoplasm into the host cell.
2. This germination is followed by merogony, during which the injected sporoplasm develops into meronts (the proliferative stage) that multiply, depending on the species, by either binary fission or multiple fission with the formation of multinucleate plasmodial forms.
3. This stage is followed by sporogony, during which meront cell membranes thicken to form sporonts that, after subsequent division, give rise to sporoblasts that go on to form mature spores without additional multiplication. Once a host cell becomes distended with mature spores, the cell ruptures, releasing mature spores into the environment and completing its life cycle. The combination of multiplication during both merogony and sporogony results in a large number of spores being produced from a single infection and illustrates the enormous reproductive potential of these organisms.

## EPIDEMIOLOGY

Microsporidia appear to be common self-limited or asymptomatic enteric pathogens in immunocompetent hosts.<sup>10,48</sup> There have been multiple reports of *Encephalitozoon bienersi* in travelers and residents of tropical countries,<sup>4,48–56</sup> as well as reports of *Encephalitozoon intestinalis*.<sup>57</sup> Serosurveys in humans have demonstrated a high prevalence of antibodies to *Enc. cuniculi* and *Enc. hellem*, suggesting asymptomatic infection is common.<sup>5,58</sup> In HIV-positive Czech patients, 5.3%

were seropositive to *Enc. cuniculi* and 1.3% to *Enc. hellem*.<sup>59</sup> In Slovakia, 5.1% of slaughterhouse workers were seropositive to *Encephalitozoon* spp.<sup>60</sup> Singh and colleagues found positive antibody titers in 8.6% of healthy adults in England, 43% of Nigerians with tuberculosis, 19% of Malaysians with filariasis, and 36% of Ghanians with malaria.<sup>11</sup> In another study, 12% of travelers returning from the tropics were seropositive and no control nontravelers were positive.<sup>12</sup> Antibodies to *Enc. intestinalis* were found among 5% of pregnant French women and 8% of Dutch blood donors.<sup>61</sup>

*Enterocytozoon bienersi* causes the majority of infections in patients with AIDS and presents as diarrhea with wasting syndrome. Infections with *Ent. bienersi* have been reported in liver and in heart-lung transplantation recipients, and *Encephalitozoon* spp. infections have been reported in patients with kidney, pancreas, liver, or bone marrow transplantation.<sup>62–69</sup> Reported prevalence rates in the 25 studies conducted on patients with HIV infection before the widespread use of highly active antiretroviral therapy (1989 to 1998) varied between 2% and 70%.<sup>2,8–10,36,70–75</sup> When combined, these studies identify 375 cases of *Ent. bienersi* among 2400 patients with chronic diarrhea for a prevalence rate of 15% in this population. With immune reconstitution due to highly active antiretroviral therapy, the incidence of microsporidiosis has decreased.

Microsporidian spores are commonly found in surface water, and human pathogenic species have been found in municipal water supplies, tertiary sewage effluent, and groundwater.<sup>51,76–78</sup> Water contact has been found to be an independent risk factor for microsporidiosis in some studies<sup>79,80</sup> but not in others.<sup>81,82</sup> *Encephalitozoon cuniculi* spores are viable for at least 6 days in water.<sup>83</sup> Most microsporidian infections are transmitted

Microsporidia  
 ■ Microsporidia

by oral ingestion of spores, with the site of initial infection being the gastrointestinal tract. Microsporidia of the genus *Encephalitozoon* are widely distributed parasites of mammals and birds,<sup>79</sup> and the onset of microsporidiosis has been associated with exposure to livestock, fowl, and pets,<sup>10,14,84,85</sup> suggesting that microsporidiosis may be a zoonosis. In Mexico, spores of *Enc. intestinalis* were identified by fluorescent antibody and PCR methods in the feces of a goat, donkey, cow, and pig.<sup>85</sup> *Enterocytozoon bieneusi* has been reported in pigs,<sup>86</sup> dogs,<sup>87</sup> chickens,<sup>88</sup> and simian immunodeficiency virus (SIV)-infected rhesus monkeys.<sup>89,90</sup> Viable infective spores of Microsporidia are present in multiple human body fluids (e.g., stool, urine, and respiratory secretions) during infection.<sup>91</sup> Person-to-person transmission is supported by concurrent infections in cohabitating homosexual men.<sup>9</sup> It has been possible to transmit *Encephalitozoon* spp. via rectal infection in rabbits, suggesting the possibility of sexual transmission.<sup>92</sup> *Encephalitozoon hellem* has been demonstrated in the respiratory mucosa, prostate, and urogenital tract of patients, raising the possibility of respiratory and sexual transmission in humans.<sup>93,94</sup> Although congenital transmission of *Enc. cuniculi* has been demonstrated in rabbits, mice, dogs, horses, foxes, and squirrel monkeys, it has not been demonstrated in humans.<sup>95</sup>

## DISEASES

### Microsporidian Infection in Immunosuppressed Hosts

Although the majority of reported cases of Microsporidia involve diarrhea, the spectrum of diseases caused by these organisms has expanded to include keratoconjunctivitis, disseminated disease, hepatitis, myositis, sinusitis, kidney and urogenital infection, ascites, cholangitis, and asymptomatic carriage.<sup>13,36,96</sup> *Encephalitozoon bieneusi* infection usually involves chronic diarrhea of 3 to 10 bowel movements per day,<sup>36,43,97–99</sup> anorexia, weight loss, and bloating without associated fever. It occurs more commonly in patients with AIDS having CD4+ counts less than 50 cells/mm<sup>3</sup>. Diarrhea is often associated with malabsorption, weight loss, and wasting syndrome.<sup>97</sup> The mortality of patients with advanced HIV disease and chronic diarrhea with wasting has been reported to be in excess of 50%.<sup>99,100</sup> In patients undergoing liver and bone marrow transplantation,<sup>62–69,101–104</sup> clinical manifestations have included watery, nonbloody diarrhea; nausea; and diffuse abdominal pain. *Encephalitozoon bieneusi* can also invade cholangioepithelium,<sup>100</sup> leading to sclerosing cholangitis, AIDS cholangiopathy, and cholecystitis,<sup>105</sup> with associated abdominal pain, nausea, vomiting, and fever. Imaging studies (abdominal ultrasound, computed tomography, endoscopic ultrasonography, and endoscopic retrograde cholangiopancreatography) usually demonstrate dilated biliary ducts, irregularities of the bile duct wall, and gallbladder abnormalities such as thickening, distention, or the presence of sludge. Systemic dissemination is rare. There is one case report describing this organism in nasal mucosa<sup>106</sup> and there are two case reports of respiratory tract involvement with *Ent. bieneusi* associated with chronic diarrhea, persistent cough, dyspnea, wheezing, and chest radiographs with interstitial infiltrates.<sup>97,107</sup>

*Encephalitozoon cuniculi*, *Enc. hellem*, and *Enc. intestinalis* (previously known as *Septata intestinalis*) been associated with

gastroenteritis, keratitis, sinusitis, bronchiolitis, nephritis, cystitis-ureteritis, urethritis, prostatitis, hepatitis, fulminant hepatic failure, peritonitis, and cerebritis, as well as disseminated infection.<sup>13,43,96,108–114</sup> An *Encephalitozoon* sp. has also been reported in a case of nodular skin lesions.<sup>115,116</sup> *Encephalitozoon intestinalis* most commonly causes diarrhea<sup>117</sup> but can also cause cholangitis,<sup>32,118</sup> keratoconjunctivitis, osteomyelitis of the mandible,<sup>119</sup> upper respiratory infections, renal failure, keratoconjunctivitis, and disseminated infection in patients with AIDS.<sup>118–122</sup> Elimination of this parasite from patients with diarrhea following treatment with albendazole correlates with the resolution of symptoms.<sup>120,123</sup> *Encephalitozoon cuniculi* has been associated with hepatitis,<sup>124</sup> peritonitis,<sup>111</sup> hepatic failure,<sup>112</sup> disseminated disease with fever,<sup>113</sup> renal insufficiency, and intractable cough.<sup>125</sup> Cases of encephalitis and seizures due to *Enc. cuniculi* have been reported in AIDS patients.<sup>113,114</sup> These infections have been reported to respond to albendazole.<sup>108,113,114,125</sup> *Encephalitozoon hellem* has been reported to cause disseminated disease associated with renal failure, nephritis, pneumonia, bronchitis, sinusitis, and keratoconjunctivitis.<sup>94,126–128</sup>

Of the reports in the literature of ocular infection due to Encephalitozoonidae, most have been attributed to *Enc. hellem*, including three cases originally classified as *Enc. cuniculi*.<sup>129,130</sup> Patients present with bilateral coarse punctate epithelial keratopathy and conjunctival inflammation resulting in redness, foreign body sensation, photophobia, excessive tearing, blurred vision, and changes in visual acuity. Ocular microsporidian infection in HIV-1-infected patients has been restricted to the superficial epithelium of the cornea and conjunctiva (i.e., superficial keratoconjunctivitis) and rarely progresses to corneal ulceration. Physical examination reveals conjunctival hyperemia with superficial punctate keratopathy, and slit-lamp examination usually demonstrates punctate epithelial opacities, granular epithelial cells with irregular fluorescein uptake, conjunctival injection, superficial corneal infiltrates, and a noninflamed anterior chamber (Fig. 96-4). Ocular infection is often associated with disseminated disease,<sup>126,131–134</sup> and thus urine examination often demonstrates microsporidian spores.<sup>126,131–134</sup>

**FIGURE 96-4** Slit lamp photomicrograph demonstrated punctate epithelial keratopathy in a patient with AIDS and microsporidian keratoconjunctivitis due to *Encephalitozoon hellem*. (From Schwartz DA, Visvesvara GS, Dieneshouse MC, et al: Pathologic features and immunofluorescent antibody demonstration of ocular microsporidiosis [*Encephalitozoon hellem*] in seven patients with acquired immunodeficiency syndrome. Am J Ophthalmol 115:285–292, 1993.)

*Trachipleistophora hominis* has been described in several patients with AIDS as a cause of disseminated disease,<sup>34</sup> with associated myositis, sinusitis, and keratoconjunctivitis. *Trachipleistophora anthropophthera* was described in several patients with AIDS having encephalitis associated with myositis and keratoconjunctivitis.<sup>35,135</sup> *Brachiola vesicularum* was reported as a cause of myositis,<sup>30</sup> as was *Pleistophora* sp (*Pleistophora ronneafiei*).<sup>136–139</sup> The presentation of these microsporidian myositis cases has included myalgias, weakness, elevated serum creatinine phosphokinase and aldolase levels, and abnormal electromyography consistent with inflammatory myopathy.<sup>30,34,137,138</sup> A fatal infection in a 4-month-old athymic male infant with severe diarrhea and malabsorption was demonstrated to be due to *Brachiola* (*Nosema*) *connori* at autopsy, where Microsporidia were seen in the lungs, stomach, small and large bowel, kidneys, adrenal glands, myocardium, liver, and diaphragm.<sup>140</sup> A case of urinary tract infection and prostatitis due to *Vit. corneae* has also been reported in a patient with AIDS.<sup>141</sup> In a child with leukemia, skin infection was due to *B. algerae* and spores were seen infecting the cellular elements of the dermis.<sup>142</sup>

### Microsporidian Infection in Immunocompetent Hosts

In patients with or without HIV infection, the most common symptom of microsporidian infection is diarrhea.<sup>3,4,9,49,53,57,62,63,79,143</sup> *Encephalitozoon bienersi* has been identified as a cause of self-limited diarrhea in immunocompetent patients and travelers<sup>9,48,55–57,144,145</sup> and has been found in up to 10% of African children with diarrhea.<sup>2,146,147</sup> *Encephalitozoon intestinalis* was found in 8% of the stools of patients in a survey for the etiology of diarrhea in Mexico<sup>79</sup> and has been seen in travelers with chronic diarrhea.<sup>57</sup> Cerebral infections due to *Enc. cuniculi* are described in several mammals but have been reported only rarely in immunocompetent humans. In a 3-year-old boy with seizures and hepatomegaly, *Encephalitozoon* infection was suggested by positive immunoglobulin G (IgG) and IgM indirect immunofluorescence assays (using *Enc. cuniculi* as the antigen).<sup>58</sup> Similarly, *Encephalitozoon* spp. infection was reported in a 9-year-old Japanese boy with headache, vomiting, spastic convulsions, and recurrent fever.<sup>17</sup> *Pleistophora* spp. have been identified in the skeletal muscle of an HIV-negative patient with myositis.<sup>136–138,148</sup> *Brachiola algerae* causing myositis with significant elevations in creatine phosphokinase (CPK) and muscle pain has been seen in a patient with rheumatoid arthritis treated with steroids and antibody to tumor necrosis factor- $\alpha$ .<sup>149</sup>

Ocular infections with ulcer or deep cornea stroma infection associated with eye pain have been reported in immunocompetent patients. In 1981, corneal microsporidiosis due to *Microsporidium africanus*<sup>150</sup> was described, and in 1973 infection due to *Microsporidium ceylonensis* was described.<sup>151</sup> Other cases of microsporidian keratitis have since been identified in immunocompetent hosts.<sup>13</sup> One of these organisms was classified as *N. oculorum*<sup>152</sup> and the other, which was successfully propagated in vitro, was named *N. corneum*<sup>153</sup> (now *V. cornea*<sup>29</sup>). *Brachiola algerae* infection of the cornea has also been reported.<sup>142</sup> In these immunocompetent patients with corneal infections, one patient required enucleation,<sup>150</sup> one underwent unsuccessful penetrating keratoplasty,<sup>151</sup> one was successfully treated with a corneal transplant,<sup>152</sup> and the last was maintained

on a variety of topical agents without effect until keratoplasty.<sup>154</sup> *Encephalitozoon* spp. corneal infections have been described in contact lens wearers.<sup>155</sup>

### PATHOGENESIS AND IMMUNITY

Infection of the epithelium of the gastrointestinal tract (small intestine and biliary epithelium) is the most frequent presentation of microsporidiosis. *Encephalitozoon bienersi* infection does not produce active enteritis or ulceration, but infection results in variable degrees of villus blunting and crypt hyperplasia. The organism is located on the apical surface of the enterocytes of the small intestine and epithelial cells of the biliary tract and pancreas. Spores are rarely found on the basal surface or in the lamina propria.<sup>110,156</sup> Infection may be associated with increased intraepithelial lymphocytes and epithelial disarray. *Encephalitozoon intestinalis* and other *Encephalitozoon* spp. are invasive; spores are found in the apical and basal sides of infected intestinal enterocytes and in the lamina propria.<sup>157</sup> Histopathology can demonstrate areas of necrosis and mucosal erosion.

*Encephalitozoon* spp. infect the genitourinary system in most mammals, including humans,<sup>48,110,120,158</sup> in which infection discovered in any organ (eye, gastrointestinal tract, liver, central nervous system, etc.) is often associated with the shedding of spores in the urine. Granulomatous interstitial nephritis composed of plasma cells and lymphocytes is the most frequent pathologic finding. This is associated with tubular necrosis, with the lumen of the tubules containing amorphous granular material. Spores are located in the necrotic tubes and sloughing tubular epithelial cells.<sup>64,68,102,104</sup> As spores and infected tubular cells are shed into the bladder, they can infect other epithelial cells of the urogenital tract, causing ureteritis, prostatitis, and cystitis<sup>110</sup> and infection in macrophages, muscle, and supporting fibroblasts of the associated mucosa.

Lower respiratory tract infection due to *Encephalitozoon* spp. has demonstrated erosive tracheitis, bronchitis, and bronchiolitis.<sup>159,131</sup> In most cases, organisms are found in intact or sloughed epithelial cells. Sinus biopsies in AIDS patients with chronic sinusitis and microsporidiosis have demonstrated spores in epithelium as well as in supporting structures.<sup>128,160–166</sup>

Infection with *Enc. cuniculi*, *Enc. hellem*, or *Enc. intestinalis* can result in punctate keratopathy and conjunctivitis that is characterized by multiple punctate corneal ulcers (e.g., a superficial epithelial keratitis). Microsporidian spores are present in corneal and conjunctival epithelium that can be obtained by scraping or biopsy of the lesions. The organisms do not invade the corneal stroma but remain limited to the epithelium. Inflammatory cells are rarely present.<sup>84,91,124,167,168</sup> Infections in immunocompetent hosts with other species of Microsporidia have usually involved deeper levels of the corneal stroma with associated necrosis and acute inflammatory cells, with some giant cells in several cases. Clinically, these patients have a corneal stromal keratitis and occasionally a uveitis.

### DIAGNOSIS

#### Copropodiagnosis

Examination by light microscopy of stool specimens using special stains is the practical method for the diagnosis of gastrointestinal microsporidiosis. Experience is greatest with

**Box 96-1** Weber's Chromotrope-Based Staining**Stain Preparation**

The chromotrope-based staining solution is prepared by mixing 6.0 g of chromotrope 2R, 0.15 g of fast green, and 0.7 g of phosphotungstic acid. After standing for 30 minutes in 3 mL of glacial acetic acid, these ingredients are mixed with 100 mL of distilled water. Acid alcohol for rinsing is prepared with 4.5 mL of acetic acid and 995.5 mL of 90% ethyl alcohol. Chromotrope staining solutions are also commercially available.

**Slide Preparation**

Ten-microliter aliquots of a suspension of unconcentrated stool fixed in 10% formalin are spread very thinly onto a glass slide. Smears are fixed in methanol for 5 minutes and stained for 90 minutes. After staining, slides are rinsed in acid alcohol for 10 seconds and then rinsed briefly in 95% alcohol. Smears are then successively dehydrated in 95% alcohol for 5 minutes, 100% alcohol for 10 minutes, and Hemo-De (a xylene substitute) for 10 minutes. The slides are scanned at  $\times 1000$  magnification (oil immersion).

Weber's chromotrope-based stain<sup>169</sup> (Box 96-1). Some laboratories prefer the Ryan modification,<sup>170</sup> which uses aniline blue in place of fast green. Using these chromotrope 2R stains, spores appear as 1- to 3- $\mu\text{m}$  ovoid light pink structures with a beltlike stripe girding them diagonally and equatorially. *Enterocytozoon* spores are smaller (0.1  $\times$  1.5  $\mu\text{m}$ ) than *Encephalitozoon* spores (1.0 to 1.5  $\times$  2.5 to 3.0  $\mu\text{m}$ ). The Gram-chromotrope stain (Box 96-2; Plate 96-1) combines chromotrope 2R staining with a Gram-staining step and results in violet-staining spores,<sup>171</sup> and it can be performed in 11 minutes. Spores can also be visualized by ultraviolet (UV) microscopy using chemofluorescent optical brightening agents such as Calcofluor white M2R (fluorescent brightener 28,

Fungi-Fluor)<sup>172</sup> or Uvitex 2B (Fungiquil A),<sup>173</sup> which stain chitin in the spore wall. Chemofluorescent stains also stain fungi, but microsporidian spores can be distinguished from yeast because they have a uniform oval shape and are non-budding. The limit of detecting Microsporidia by these light microscopy techniques appears to be 50,000 organisms/mL.<sup>174</sup> Overall, the sensitivity of the chemofluorescent brightener-based stains is slightly higher than that of chromotrope-based stains (especially when low numbers of spores are present in a sample); however, the specificity of the chemofluorescent stains is lower (90% vs. 100% in one study).<sup>174</sup> It has been reported that microsporidian spores in food can give a false-positive result, but this does not appear to be a common

**Box 96-2** Description of the Quick-Hot**Gram-Chromotrope Staining Technique for Microsporidia, for Use with the Slide Stainer\***

- A. Prepare a thin smear of the material to be stained (e.g., feces, urine, sputum, saliva, and cell culture supernatants) and air dry.
- B. Heat-fix smear (three times for 1 second each over a low flame or 5 minutes on a slide warmer at 60°C). Cool to room temperature before staining.  
Note: For formalin-fixed, paraffin-embedded tissue sections, deparaffinize as usual, hydrate in a series of alcohols, and bring the slides to water before performing Gram's stain.
- C. Perform Gram's stain (without the safranin step).  
We followed the Gram staining procedures as described in either the Gram Stain Kit SG100 or Carr-Scarborough and Boekel Slide Stainer brochure, with slight modifications as follows:
  - C1. Dip slides into well containing gentian violet solution and let stand for 30 seconds.<sup>†</sup>
  - C2. Rinse off excess stain gently with water.
  - C3. Dip slides into well with Gram's iodine solution and allow to remain on the slide for 30 seconds.<sup>†</sup>
  - C4. Remove Gram's iodine solution by gently rinsing with decolorizer solution. Hold the slide at an angle and add the decolorizer solution dropwise until it flows off the slide colorless.<sup>‡</sup>
  - C5. Wash slide gently with cold water to remove excess decolorizer solution.
- D. Perform chromotrope stain.
  - D1. Place the slide in warm (50°C to 55°C) chromotrope stain (1.0 g chromotrope 2R [Mallinckrodt], 0.15 g fast green, 0.25 g phosphotungstic acid, 3 mL acetic acid, and 100 mL distilled water) for at least 1 minute.<sup>†</sup>
  - D2. Rinse in 90% acid alcohol (4.5 mL acetic acid and 995.5 mL of 90% ethyl alcohol) for 1 to 3 seconds.<sup>‡</sup>
  - D3. Rinse in 95% ethyl alcohol for 30 seconds.
  - D4. Rinse twice, 30 seconds each time, in 100% ethyl alcohol placed in two different containers; let dry.<sup>§</sup> Mount with Cytoseal 60 and examine.

\*Turn on slide stainer 15 minutes before starting to stain slides.

<sup>†</sup>For formalin-fixed, paraffin-embedded tissue sections, we recommend that the staining times be prolonged for 30 seconds in each step.

<sup>‡</sup>Take extra care during the destaining process to achieve correct staining of spores.

<sup>§</sup>For formalin-fixed, paraffin-embedded tissue sections, we recommend that the slides be washed briefly in a solution of 50% ethyl alcohol/50% xylene for 15 seconds and subsequently in 100% xylene for 15 seconds before mounting with Cytoseal 60 and without letting the slide dry.

Data from Moura and colleagues.<sup>171</sup>

problem in the use of stool specimens for diagnosis of these infections.

Because renal involvement with shedding of spores in the urine is common in all of the species of Microsporidia that disseminate, urine specimens should be obtained whenever the diagnosis of microsporidiosis is considered. This has therapeutic implications because the Microsporidia that disseminate (e.g., *Encephalitozoon*) are usually sensitive to albendazole, but those that do not disseminate (e.g., *Ent. bienewisi*) are resistant. Definitive identification of the Microsporidia causing an infection cannot be done with light microscopy and requires either ultrastructural examination (e.g., electron microscopy) or molecular techniques (e.g., species-specific PCR). If stool examination is negative in the setting of chronic diarrhea (more than 2 months' duration), then endoscopy should be performed.

### Cytologic Techniques

In body fluids other than stool (e.g., urine, cerebrospinal fluid, bile, duodenal aspirates, bronchoalveolar lavage fluid, and sputum), Microsporidia have been easily visualized using a variety of stains (e.g., Chromotrope 2R, chemofluorescent optical brightening agents, Giemsa, Brown–Hopps Gram stain, acid fast staining, and/or Warthin–Starry silver staining).<sup>43,175,176</sup> Since Microsporidia often infect mucosa or epithelium, cytologic preparations are useful for diagnosis.<sup>43</sup> Microsporidia have been easily demonstrated in intestinal and biliary epithelium, epithelium of the cornea and conjunctivae, epithelium of the sinonasal and tracheobronchial regions, renal tubular epithelium, and urothelium. Microsporidian keratitis cell samples obtained by gentle rubbing over the conjunctiva and cornea with a tissue swab usually reveal multiple, gram-positive, oval organisms within epithelial cells (Fig. 96-5).

### Histologic Techniques

Using routine procedures, microsporidian spores are discernible with a modified tissue chromotrope 2R or tissue

**FIGURE 96-5** Conjunctival smear from a patient with AIDS and *Encephalitozoon hellem* keratoconjunctivitis stained with Gram stain. Numerous gram-positive microsporidian spores can be seen within the cytoplasm of the epithelial cells as well as outside of these cells.

**FIGURE 96-6** *Encephalitozoon intestinalis* in a duodenal biopsy plastic-embedded section stained with toluidine blue. Unlike *Enterocytozoon*, the spores of *Encephalitozoon intestinalis* develop in a vacuole, termed the parasitophorous vacuole, as shown in both superficial enterocytes and in a lamina propria macrophage. (Magnification  $\times 1000$ .)

Gram stain (Brown–Hopp or Brown–Brenn) in biopsy and autopsy tissue specimens. In people with intestinobiliary infections, the jejunum and ileum (followed by the duodenum) have the greatest concentration of organisms and highest diagnostic yield (Fig. 96-6). In transbronchial biopsies, spores are best identified in bronchial or bronchiolar epithelium, but they can also be found within alveolar spaces. Microsporidia are usually gram positive and some are also acid-fast positive. Due to their thick wall, unstained spores are refractile and as such can be birefringent in unstained tissue sections. With experience, Microsporidia can also be seen on hematoxylin and eosin stain. Other stains that may be useful include periodic acid–Schiff, Giemsa, and Steiner silver stains. Biopsy or autopsy material should, if possible, also be placed in electron microscopic fixative when microsporidiosis is suspected because definitive diagnosis of species requires ultrastructural information. Although molecular methods such as PCR can be performed using formalin-fixed tissue, better results are obtained with unfixed tissue or tissue fixed in ethanol.

### Electron Microscopy, Immunofluorescence, Molecular Diagnostic Methods, Serology, and Tissue Culture

Electron microscopy is a useful technique for confirmation of microsporidian infection in patient tissues and fluids, as well as for detailed ultrastructural studies of microsporidian life cycles and host-parasite relationships that are required for the description of new species of Microsporidia (see Figs. 96-1 and 96-2). Electron microscopy should be performed on any new or atypical infections that are diagnosed as being due to Microsporidia. Fluorescent antibody reagents can be used for the species-level identification of various Microsporidia in both cytologic and tissue specimens,<sup>177–181</sup> but these are available only in research and reference laboratories. Serologic tests for the diagnosis of microsporidiosis have been developed and utilized for epidemiologic studies, but they have not been useful for the diagnosis of microsporidiosis in AIDS patients.<sup>182</sup> Molecular diagnostic techniques such as PCR are being used with increasing success and have successfully identified

Microsporidia at the species level in intestinal biopsies, stool specimens, and other tissues (for a review see Weiss and Vossbrinck<sup>40</sup>).<sup>183–186</sup> Currently, these tests are available only in reference laboratories such as the Centers for Disease Control and Prevention. The in vitro cultivation of several human-infecting Microsporidia has enhanced our understanding of these pathogens (for a review see Visvesvara<sup>187</sup>). *Vittaforma corneae*,<sup>153</sup> *Enc. cuniculi*, *Enc. hellem*,<sup>167</sup> *T. hominis*,<sup>34</sup> and *Enc. intestinalis*<sup>188</sup> have been cultivated in vitro, whereas *Ent. bienersi* has not. The isolation of Microsporidia from clinical specimens is not a routine procedure and is available only in a few specialized research laboratories.

## DIAGNOSIS

The Microsporidia are generally considered after the more common pathogens of the gastrointestinal, hepatobiliary, respiratory, genitourinary, ocular, musculoskeletal, and central nervous systems have been considered and ruled out. The index of suspicion for microsporidiosis should be highest in patients with severe immunosuppression, especially, but not exclusively, those infected with HIV. Intestinal microsporidiosis should be considered in any patient with chronic diarrhea or hepatobiliary disease of uncertain cause. The differential diagnosis includes other infectious agents characterized by chronic diarrhea, such as *Cryptosporidium*, *Cyclospora*, *Giardia*, or *Isospora*. Intestinal microsporidiosis should be considered in cases of presumptive traveler's diarrhea in which other routine pathogens have been excluded. A diagnosis of microsporidiosis should also be considered in cases of unexplained keratoconjunctivitis

or corneal ulcers, persistent sinusitis or diffuse lower respiratory disease, unexplained renal insufficiency or abnormalities in urinary sediment, and myositis. Since dissemination can occur, microsporidiosis may affect virtually any organ system, including bone and the central nervous system. Therefore, the identification of Microsporidia in any specimen should prompt a thorough search in all other readily available sources, including stool, urine, sputum, nasal and conjunctival swabs, and possibly cerebrospinal fluid, with consideration of more invasive approaches for those patients requiring a tissue-based diagnosis (e.g., myositis).

## TREATMENT AND PROGNOSIS

For a review of drugs used in microsporidiosis in humans and animals, see Costa and Weiss<sup>189</sup> (Table 96-2). Although albendazole has significant activity against many Microsporidia, such as the Encephalitozoonidae, it has limited efficacy for *Ent. bienersi* infection,<sup>190–192</sup> with relapse of symptoms rapidly occurring with the discontinuation of therapy in patients who reported improvement of symptoms with treatment. Other studies have found that albendazole has no efficacy in *Ent. bienersi* infection.<sup>193</sup> Fumagillin is used to treat honeybees infected with the microsporidian *Nosema apis* and has been used to treat microsporidiosis in aquaculture.<sup>194,195</sup> Fumagillin and its semisynthetic analogue, TNP-470, were found to have activity in vitro and in vivo against *Enc. cuniculi*, *Enc. hellem*, *Enc. intestinalis*, and *V. corneae*.<sup>196–201</sup> Fumagillin has also been demonstrated in both a dose-escalation trial and a randomized clinical trial to be effective for the treatment of human infection

**Table 96-2 Treatment Options for Microsporidiosis**

Organism	Drug	Dosage and Duration
All microsporidian infections	Restoration of immune function can be critical in control of infection. Patients with AIDS should have highly active antiretroviral therapy optimized.	
<i>Enterocytozoon bienersi</i>	No effective commercial treatment. Oral fumagillin 20 mg TID (e.g., 60 mg/day has been effective in a clinical trial. Albendazole* resulted in clinical improvement in up to 50% of patients in some studies; however, it was not effective in other studies.	
Encephalitozoonidae infection (systemic, sinusitis, encephalitis, hepatitis, etc.)		
<i>Enc. cuniculi</i>	Albendazole	400 mg BID <sup>†</sup>
<i>Enc. hellem</i>	Albendazole	400 mg BID
<i>Enc. intestinalis</i>	Albendazole	400 mg BID
Encephalitozoonidae keratoconjunctivitis	Fumagillin solution <sup>‡</sup> (Fumadil B 3 mg/mL)	2 drops every 2 hr for 4 days, then 2 drops 4 times a day <sup>§</sup>
<i>Trachipleistophora hominis</i>	Patients may also need albendazole* if systemic infection is present. Albendazole	400 mg BID
<i>Brachiola vesicularum</i>	Albendazole ± itraconazole	400 mg BID 400 mg QD

\*Albendazole 400 mg BID.

<sup>†</sup>The duration of treatment for microsporidiosis has not been established. Relapse of infection has occurred upon stopping treatment. Patients should be maintained on treatment for at least 4 weeks and most patients should be on treatment indefinitely.

<sup>‡</sup>Fumagillin bicyclohexylammonium.

<sup>§</sup>Eyedrops should be continued indefinitely; relapse is common on stopping treatment.

Adapted from Costa and Weiss.<sup>189</sup>

with *Ent. bieneusi* at a dose of 60 mg/day (20 mg TID).<sup>196,197</sup> Treatment was associated with resolution of diarrhea, clearance of spores, improvement of Karnofsky scores, and improvement in D-xylose absorption tests. The main limiting toxicity of this treatment was thrombocytopenia, which was reversible on stopping fumagillin treatment. Despite a few case reports that indicated that metronidazole was effective for *Ent. bieneusi* infection, the majority of studies have demonstrated that this drug is not effective.<sup>158,198,202</sup> Other medications used without success in the treatment of gastrointestinal microsporidiosis are azithromycin, paromomycin, and quinacrine. Clinical studies have demonstrated that improvement of immune function can result in clinical response with the elimination of the organism and normalization of intestinal architecture in gastrointestinal microsporidiosis.<sup>203–207</sup> Part of the primary treatment of microsporidiosis in the setting of AIDS is the institution of effective antiretroviral therapy.

There are numerous case reports that demonstrate the efficacy of 2 to 4 weeks of 400 mg BID of albendazole for the treatment of microsporidian infections due to *Encephalitozoon* spp. A double-blind, placebo-controlled trial of eight patients with AIDS and diarrhea due to *Enc. intestinalis* demonstrated that albendazole (400 mg BID for 3 weeks) treatment led to a resolution of the diarrhea and elimination of the organism, similar to observations in case reports.<sup>120,121,123,158,163,208,209</sup> In case reports of chronic sinusitis, respiratory infection, and disseminated infection due to *Enc. hellem*, treatment with 400 mg of albendazole twice daily resulted in resolution of symptoms and clearance of the organism.<sup>210,211</sup> In a patient with disseminated *Enc. cuniculi* infection involving the central nervous system, conjunctiva, sinuses, kidney, and lungs, clinical improvement was demonstrated with albendazole treatment.<sup>114</sup> The successful use of albendazole has also been reported in cases of urethritis,<sup>212</sup> renal failure,<sup>213</sup> and disseminated infection<sup>125</sup> due to *Encephalitozoon* spp. In addition, albendazole has been reported to have activity in the treatment of disseminated microsporidian infection with *T. hominis* and in myositis due to a *Brachiola vesicularum*.<sup>30,34</sup>

Ocular microsporidiosis can be treated with a solution of 3 mg/ml of Fumidil B (fumagillin bicylohexylammonium) in saline<sup>199,214–217</sup>; however, recurrence is known to occur when topical therapy is discontinued. Although clearance of Microsporidia from the eye can be demonstrated, the organism is still present systemically and can often be demonstrated in urine or nasal smears. The use of albendazole as a systemic agent is thus also reasonable for the treatment of ocular infection and should probably be used in addition to topical treatment. Polymyxin B, propamidine isethionate 0.1% (Brolene), gramicidin, neomycin sulfate, and tetracycline have limited efficacy and should not be used except as treatment for secondary bacterial infections. Keratoplasty provides temporary improvement in some cases, and debulking by corneal scraping may be useful in cases not responding to medical treatment. Steroids may be useful in decreasing the associated inflammatory response.

## PREVENTION AND CONTROL

The presence of infective spores in various bodily fluids suggests that body substance precautions in health-care settings and general attention to hand washing and other personal

hygiene measures should be useful in preventing primary infections. Hand washing may be particularly important in the prevention of ocular infections, which may occur as a result of inoculation of conjunctival surfaces by fingers contaminated with respiratory fluids or urine. Whether respiratory precautions are necessary for people with spores in sputum or other respiratory secretions is unknown. It is reasonable to screen close contacts of index cases of microsporidiosis. Spores survive and remain infective in the environment for prolonged periods of time.<sup>83</sup> In a typical hospital environment, *Enc. cuniculi* spores can survive and remain infectious for at least 1 month but can be rendered noninfectious by a 30-minute exposure to most common disinfectants and by the methods employed for sterilization. Therefore, the procedures used to clean most hospital rooms should be sufficient to limit infection.

It is likely that these organisms are food- or water-borne pathogens and the usual sanitary measures that prevent contamination of food and water with the urine and feces of animals should decrease the chance for infection. Existing guidelines for the prevention of opportunistic infections that address food, water, and animal contact may be useful in preventing microsporidiosis. Severely immunocompromised patients may wish to consider using bottled or filtered water in some settings. No prophylactic antiparasitic agents have been identified for these organisms. Microsporidiosis has developed in patients on trimethoprim-sulfamethoxazole prophylaxis<sup>218</sup> and those receiving dapsone, pyrimethamine, itraconazole, azithromycin, and/or atovaquone.<sup>219</sup> No studies have evaluated albendazole for prophylaxis, but given its relative lack of efficacy for *Ent. bieneusi* infections, it is unlikely to be effective for prevention. The most effective prophylaxis is a restoration of immune function in immunocompromised hosts. In AIDS patients, several studies have demonstrated that highly active antiretroviral therapy can produce remission of intestinal microsporidiosis.<sup>203–207</sup>

# Systemic Coccidia (Toxoplasmosis)

JOSEPH D. SCHWARTZMAN  
JAMES H. MAGUIRE

## INTRODUCTION

*Toxoplasma gondii* is a versatile intracellular parasite that has adapted to infect many animal species and is capable of causing a wide spectrum of disease, the preponderance of which is asymptomatic.<sup>1-3</sup> Active invasion of host cells leads to their eventual death; a complex interplay of the host cell-mediated immune response arrests the acute infection and maintains continued suppression of the persistent encysted zoites, usually for the life of the host. The wide host range of *T. gondii* is an exception to the rule of most other members of the phylum Apicomplexa. *Toxoplasma* also has a wide geographic range: its single species is found worldwide, with the exception of a very few isolated islands. The ability to infect many species by at least two routes and its broad distribution are responsible for the high prevalence of infection in the human population; perhaps a third of the world's people are chronically infected by *T. gondii*. The spectrum of disease caused by *T. gondii* does not differ with its geographic distribution. Serious illness is unusual except among persons with deficient cell-mediated immunity and infants infected in utero. Toxoplasmosis is an economically important cause of abortion in sheep, swine, and goats.<sup>4,5</sup>

## AGENT

### History and Taxonomy

In 1908, Nicolle and Manceaux<sup>6</sup> in Tunis identified *T. gondii* in a laboratory rodent, the North African gundi. In the same year, Splendore<sup>7</sup> noted identical forms in a laboratory rabbit in Brazil. Understanding of the importance of this parasite for humans did not come until 1937 when Wolf and Cowen<sup>8</sup> in New York identified it as a cause of "granulomatous encephalomyelitis." Appreciation of the role of chronic infection came with the identification by Wilder<sup>9</sup> in the 1950s of *Toxoplasma* in eyes previously thought to have been involved with tuberculosis or syphilis. The high prevalence of the infection was only realized after the serologic dye test was developed by Sabin and Feldman<sup>10</sup> in 1948. Congenital toxoplasmosis in infants was recognized before either generalized disease in adults or the lymphadenitis of primary *Toxoplasma* infections in adults was appreciated.<sup>8</sup> The role of reactivation

of latent infections in the production of disease in immunosuppressed adults was recognized at the outset of solid organ transplantation.<sup>11</sup> The onset of acquired immunodeficiency syndrome (AIDS) brought recognition of central nervous system (CNS) reactivation causing multifocal encephalitis.<sup>12</sup>

*T. gondii* is a genetically homogeneous single species with a clonal population structure.<sup>13</sup> Three genetic types make up 95% of isolates from all continents.<sup>14,15</sup> Type II strains, defined on the basis of extensive genotyping, are most commonly recovered from humans with both congenital and acquired toxoplasmosis.<sup>14</sup> Type I strains are more virulent in outbred mice, more frequent in congenital infections in some geographic areas,<sup>16</sup> and along with "atypical" strains (recombinant genotypes of type I and type II strains) are overrepresented in serious ocular infections.<sup>17</sup> Genetic evidence suggests that the clonal lineages arose approximately 10,000 years ago and spread rapidly perhaps because of concurrent acquisition of efficient oral infectivity.<sup>18-20</sup>

## Life Cycle

The asexual stages of *T. gondii* are pathogenic for man and animals.<sup>21</sup> Two forms are produced, a rapidly dividing, invasive tachyzoite in all tissues, and a slowly dividing bradyzoite in cysts predominantly found in brain and muscle<sup>1,22</sup> (Figs. 97-1 and 97-2). Tachyzoite replication causes acute disease, while the bradyzoite cyst is long-lived, with slow turnover, and is responsible for latency and reactivation. Reservoirs of human infection are birds and rodents ingested by cats, as well as human food animals, especially pigs, goats, and sheep, which can carry orally infectious cysts in meat.<sup>4,5,23</sup> The sexual stage is found in the small intestinal epithelium of both wild and domestic Felidae. Oocysts, the end product of the sexual cycle, are resistant to environmental conditions, tend to float in watered soils, and thereby remain in the superficial layers where they may be ingested by contamination of vegetables or hands.<sup>24,25</sup> Oocysts sporulate within 12 to 24 hours to several days after passage from the cat and are thereafter infectious.

**FIGURE 97-2** Congenital toxoplasmosis. Tissue cysts in uvea of human eye with numerous intracellular bradyzoites. (Hematoxylin and eosin,  $\times 1000$ .) (Courtesy of the Department of Tropical Public Health, Harvard School of Public Health, Boston, MA.)

## ECOLOGY, EPIDEMIOLOGY, AND DISTRIBUTION

Humans may be infected both by eating cysts in meat and by ingestion of oocysts from contaminated soil. The relative risk of infection in industrialized countries is considered to be higher from the ingestion of undercooked meat, especially lamb and beef, but in societies with little meat in the diet, oocysts are more important.<sup>26</sup> Birds and rodents are important in picking up oocysts from soil and scavenging bradyzoite cysts from infected animals.<sup>1,27</sup> Grazing food animals (e.g., sheep) are probably infected by soil oocysts, but swine are omnivores and may also ingest infected rodents.<sup>3–5</sup> The prevalence of *Toxoplasma* in swine is quite variable. Bovine and fowl *Toxoplasma* levels are low, but the high consumption of beef may explain the association with acquired toxoplasmosis.<sup>28–29</sup> Although sexual recombination has been shown to take place in cats, it appears to be rare in nature.<sup>17,24,25,30</sup> The distribution of *T. gondii* is worldwide; all genotypes are found on all continents except Antarctica. Islands without *T. gondii* have been found in the Pacific, and along the coast of Central America.<sup>26,31,32</sup> Hot, dry climates have a lower incidence of toxoplasmosis than temperate, moist climates, and rates are low at high altitudes.<sup>26,33,34</sup> Geographic foci of transmission by oocysts (cat cycle) have been described in societies that do not consume meat.<sup>35</sup> The role of the cat in the transmission of toxoplasmosis is established, but the epidemiology of transmission includes the possible role of dogs. Dogs have been proposed as vectors of oocysts based on associations in epidemiologic surveys and their habit of rolling in cat feces or eating cat feces.<sup>27</sup> River water contaminated with oocysts was believed to be the source of an outbreak in a Panamanian jungle.<sup>36</sup> Public water supplies were implicated in an outbreak in British Columbia, and drinking unfiltered municipal and surface water were associated with a high level of endemicity in Rio de Janeiro State, Brazil.<sup>31,32</sup> *Toxoplasma* infection also is acquired by transplacental transmission<sup>2</sup> and, less commonly, through organ transplantation<sup>11</sup> and laboratory accident.<sup>37</sup> Although *Toxoplasma* DNA can be detected by polymerase chain reaction (PCR) in blood from chronically infected

persons,<sup>38</sup> transmission of toxoplasmosis by transfusion of banked blood has not posed a public health problem.<sup>39</sup> Man is a dead-end host for *T. gondii*, which is of importance in the potential epidemiology of drug resistance.

Serologic surveys demonstrate prevalences of infection from less than 10% to greater than 90% in various geographic locations.<sup>2,40–50</sup> In parts of France, where rates of infection may exceed 90% by the fourth decade,<sup>2,40,41</sup> transmission appears to be related to ingestion of rare or raw meat. In contrast, rates in England and Finland are approximately 20%.<sup>42,43</sup> In moist tropical areas of Latin America and sub-Saharan Africa, where cats are abundant and the climate favors survival of oocysts, the prevalence may approach 90%.<sup>26,27,44–48</sup> In comparison, rates in hot, dry regions such as North Africa usually do not exceed 20%.<sup>49</sup> Rates in the United States also vary, ranging from 3% in Denver, Colorado, to 17% in Massachusetts, and to 30% in Birmingham, Alabama.<sup>2,50</sup> The seroprevalence of toxoplasmosis among persons aged 12 to 49 years in the United States remained stable at around 16% throughout the 1990s.<sup>51</sup>

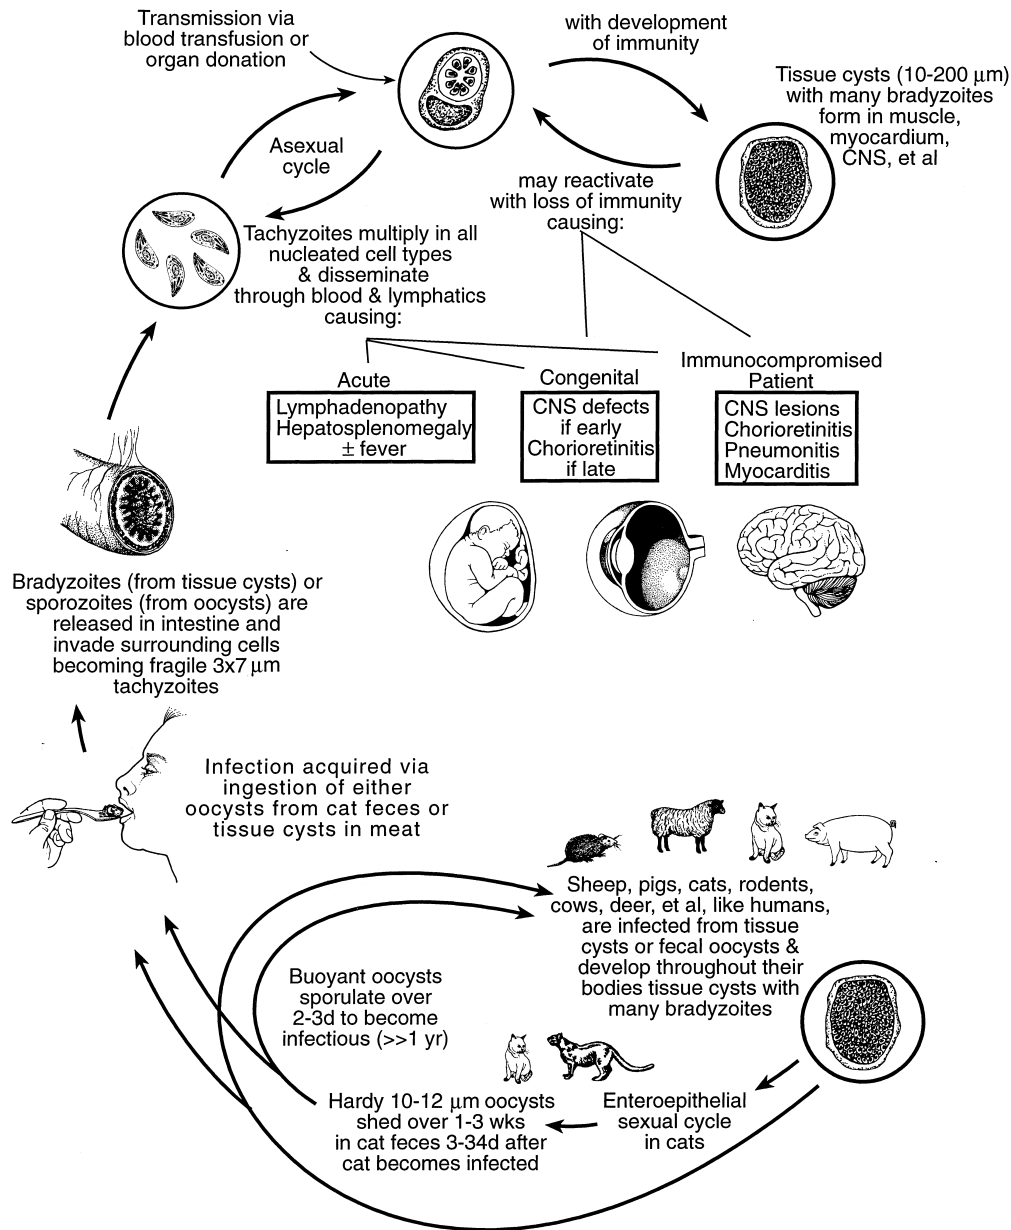

## PATHOGENESIS, PATHOLOGY, AND CLINICAL MANIFESTATIONS

### Primary Disease

The primary route of infection is oral, with progression of the infection through the gastrointestinal tract to local lymphatics and spread to other organs documented in the mouse, but this has not been followed step by step in humans.<sup>2,22,50,52</sup> In mice fed bradyzoites, the first step appears to be local invasion of the small intestinal epithelium. The bradyzoite and tachyzoite are both capable of active invasion of many cell types and replicate within a parasite-modified vacuole.<sup>52–58</sup> Bradyzoites rapidly convert to tachyzoites in vivo. In vitro, the formation of bradyzoite cysts can be stimulated by various maneuvers that stress the infected cells.<sup>59,60</sup> The key step in spreading the infection from the localized initial site is likely infection of circulating monocytes in the lamina propria; this cell subset has been shown to be permissive for *T. gondii* replication in both mice and humans and may therefore be responsible for transport of the parasite widely throughout tissues.<sup>22,52,61</sup>

Tachyzoites are found in all organs in acute infection, most prominently in muscle, including heart, and in the liver, spleen, lymph nodes, and the CNS.<sup>2,50,52</sup> The initial pathologic lesion is necrosis caused by death of parasitized cells, with a vigorous acute inflammatory reaction. As the disease progresses, more lymphocytic infiltration develops, but true granulomas are not formed. If the host controls the replication of tachyzoites effectively, tissues are restored to anatomical integrity without scarring, and cysts containing the long-lived bradyzoites remain without sign of host reaction.<sup>62</sup> The humoral immune response is rapid and may be capable of killing extracellular tachyzoites (and is of use diagnostically), but it is not protective in the mouse model.<sup>61</sup> Control of the disease appears to depend on the elaboration of appropriate cytokines including interleukin (IL)-2, IL-12, and interferon- $\gamma$  (INF- $\gamma$ )<sup>63–65</sup> followed by a specific cell-mediated immunity with CD8+ helper T cells apparently the most important subgroup.<sup>66–68</sup> In some experimental infections, there is intense acute inflammation with few identifiable parasites and early death, which

# *Toxoplasma gondii*

may be caused by an overly vigorous cytokine response to the infection.<sup>69</sup>

Subclinical or unrecognized infection is the usual outcome of primary infection in immunocompetent persons.<sup>1,2,36,70-75</sup> When symptoms occur, the most common manifestation is painless lymphadenopathy, with or without fever.<sup>50,74</sup> Usually a single cervical node is enlarged, but there may be multiple enlarged nodes at one site or generalized lymphadenopathy. Toxoplasmic lymphadenopathy may persist for 4 to 6 weeks, raising the suspicion of lymphoma.<sup>74,76</sup> Occasionally, a syndrome of fever, headache, malaise, myalgia, lymphadenopathy, hepatosplenomegaly, and atypical lymphocytosis develops after an incubation period of 5 to 20 days.<sup>36,71-73</sup> The course

of illness may last weeks or months, suggesting a diagnosis of infectious mononucleosis. Pneumonitis, myocarditis, meningoencephalitis, polymyositis, and death are rare complications in otherwise healthy persons.<sup>77,78</sup> In Brazil and British Columbia, a high incidence of acute acquired retinochoroiditis has been described.<sup>79,80</sup> Retinochoroiditis in primary acute infection is more common than previously has been considered and may be associated with particular genotypes.<sup>81</sup>

## Congenital Disease

Primary infection of the mother and infection of the placenta is the mechanism by which almost all congenital disease

is transmitted.<sup>2,34,82–84</sup> The placenta is an imperfect barrier to infection of the fetus and allows transmission to the fetus in 30% to 50% of infections acquired during pregnancy.<sup>2,82</sup> Congenital infection is exceptionally rare when the mother acquires infection before gestation,<sup>85,86</sup> and most of the few reported cases have occurred when maternal infection occurred within 3 months of conception or in the setting of maternal immunosuppression due to human immunodeficiency virus (HIV) infection or immunosuppressive therapy.<sup>87,88</sup> Acute infection is apparent in fewer than 20% of mothers, but both symptomatic and asymptomatic infections place the fetus at risk. The rate of transplacental transmission and the severity of disease vary with time of gestation.<sup>2,87</sup> If maternal infection occurs during the first trimester, the risk of fetal infection is only around 10%, but disease is usually severe. Rates of congenital infection rise to about 65% for maternal infection during the third trimester and approach 100% at term, but neonatal infection in these instances usually is asymptomatic.<sup>34</sup>

Overall, fewer than 15% of infants with congenital toxoplasmosis have severe impairment of the brain or eyes, and about 80% are asymptomatic at birth or have mild disease that is not detected by routine physical examination.<sup>82,89–92</sup> However, more than 85% of those with asymptomatic infection will develop adverse sequelae of the CNS or eyes in subsequent years.<sup>91,92</sup>

Early fetal infections lead to spontaneous abortion, stillbirth, or severe neonatal disease.<sup>2,52,84</sup> In the brain, there are foci of necrosis, microglial nodules, and perivascular mononuclear inflammation in association with free and intracellular tachyzoites.<sup>2,52</sup> Vascular thrombosis may lead to large areas of coagulation necrosis. Necrosis around ventricles or the aqueduct of Sylvius may lead to hydrocephalus, and areas of necrotic brain become calcified. Neurologic sequelae include seizures, psychomotor retardation, deafness, hydrocephalus, microcephalus, and prominent intracerebral calcifications visible on radiographs (Fig. 97-3). A common feature of

**FIGURE 97-3** Intracerebral calcifications and mild hydrocephalus in an infant with congenital toxoplasmosis. Computed tomography scan of the head without contrast.

**FIGURE 97-4** Healed retinochoroiditis in the periphery of the fundus of the eye of an adult who had documented congenital toxoplasmosis.

severe congenital toxoplasmosis is bilateral retinochoroiditis manifested by necrosis of the retina and granulomatous inflammation of the choroid.<sup>93</sup> Lesions are near to or in the macula, and vitritis and uveitis are frequently present. There may be micro-ophthalmia, strabismus, cataracts, glaucoma, and optic atrophy. Systemic manifestations such as fever, hypothermia, jaundice, vomiting, diarrhea, lymphadenopathy, hepatosplenomegaly, pneumonitis, myocarditis, and rash may be present.<sup>2,90</sup> Laboratory studies show anemia, thrombocytopenia, high cerebrospinal fluid (CSF) protein, and CSF pleocytosis.

While the majority of infants who acquire infection late in pregnancy appear normal at birth, meticulous examination often shows abnormalities such as retinal scars (Fig. 97-4) or abnormal CSF.<sup>89,90</sup> Healthy-appearing infants occasionally develop severe CNS or ocular disease during the first months of life. More commonly, persons with asymptomatic infections at birth experience recurrent episodes of retinochoroiditis or impaired psychomotor development during the first 10 to 20 years of life.<sup>91,92</sup>

### Ocular Disease

Toxoplasmosis may account for as many as one third of cases of retinochoroiditis.<sup>93–95</sup> Most cases occur in teenagers and young adults and in the past have been ascribed to reactivation of congenitally acquired infection. Population-based studies in southern Brazil and recent experience with clusters of acute disease in adults have shown that acquired infection may account for more cases of retinochoroiditis than congenital infection.<sup>79–81,96,97</sup> Active disease causes pain, photophobia, and blurred vision in the absence of constitutional symptoms. On funduscopic examination, the vitreous is hazy, and elevated, pale-yellow, or white cotton-like patches are seen in the retina. Healed scars are pale with distinct margins and prominent black spots of choroidal pigment. Recurrent retinochoroiditis usually occurs at the borders of scars and may lead to blindness.

### Disease in Persons with AIDS and Other Causes of Immunodeficiency

Toxoplasmosis is life-threatening for persons with impaired cellular immunity, in particular those with HIV infections and CD4+ T-cell counts less than 100/ $\mu$ L of blood and persons receiving immunosuppressive medications.<sup>11,12,98</sup> Disease in these persons is more commonly due to reactivation of chronic infection than to newly acquired infection.<sup>99,100</sup> Historically, approximately one-third or more of AIDS patients with antibodies to *Toxoplasma* reactivated their latent infection, but with the widespread use of antimicrobial drugs to prevent *Pneumocystis jirovecii* pneumonia and highly active antiretroviral therapy (HAART), the incidence of reactivation and toxoplasmosis-associated deaths has decreased.<sup>101,102</sup> Because of the high prevalence of chronic *Toxoplasma* infection in tropical climates, reactivated toxoplasmosis is a more frequently observed opportunistic infection among HIV-infected immigrants from developing regions than among HIV-infected natives of industrialized countries.<sup>103</sup> In many tropical regions, reactivation of toxoplasmosis is less common than might be expected because of the short life expectancy of HIV-infected persons due to other causes.<sup>104</sup> Persons who receive chemotherapy for organ transplantation or treatment of lymphomas and leukemia are particularly susceptible to toxoplasmosis, although rates of reactivation in these persons are not as great as those among persons with AIDS.<sup>11,105,106</sup> Transplantation of *Toxoplasma*-infected organs (especially hearts) places antibody-negative recipients at risk of severe generalized toxoplasmosis.<sup>107–109</sup> Immunodeficient persons who receive leukocyte transfusions are also at risk of acquiring toxoplasmosis.<sup>110</sup>

The predominant manifestation of toxoplasmosis in immunocompromised persons is multifocal necrotizing encephalitis<sup>12,98,99</sup> (Fig. 97-5). Patients present with altered level of consciousness, headache, focal neurologic deficits, seizures, and often fever. Computed tomography (CT) and magnetic resonance (MR) scans of the head typically demonstrate multiple low-density lesions at the corticomedullary junction or in the basal ganglia that enhance following the administration of intravenous contrast (Fig. 97-6). There is often a mononuclear CSF pleocytosis and mild elevation of

**FIGURE 97-5** Section of brain showing lesions of toxoplasmosis at autopsy of a patient with acquired immunodeficiency syndrome (AIDS).

**FIGURE 97-6** Magnetic resonance (MR) image of the brain showing a ring-enhancing hypodense lesion and surrounding edema in a patient with CNS toxoplasmosis and AIDS.

protein, but meningeal signs are uncommon. After the brain, the lungs and heart are the next most frequently involved organs in immunocompromised persons. Toxoplasmic myocarditis is frequently subclinical,<sup>111</sup> while a syndrome of rapidly progressive pulmonary infiltrates and shock may evolve when there is pulmonary infection.<sup>112,113</sup> Generalized toxoplasmosis is also seen in immunocompromised patients, and involvement of liver, spleen, lymph nodes, pancreas, intestines, thyroid, peritoneum, testes, retina, and spinal cord has been documented.<sup>98,99,114–116</sup> Without treatment, CNS toxoplasmosis and other severe forms of the disease in compromised hosts are fatal.

### DIAGNOSIS

#### Differential Diagnosis

Because the differential diagnosis of the various forms of toxoplasmosis is broad, diagnostic confirmation in the laboratory is essential in most cases. Acute toxoplasmosis in healthy persons must be differentiated from mononucleosis due to Epstein-Barr virus or cytomegalovirus, acute HIV infection, other viral infections, cat-scratch disease, tuberculosis, fungal diseases, secondary syphilis, tularemia, African and American trypanosomiasis, visceral leishmaniasis, Hodgkin's disease, lymphoma, and sarcoidosis. The differential diagnosis of congenital toxoplasmosis includes congenital infections due to cytomegalovirus, *Herpes simplex*, rubella, *Listeria*, syphilis, *Trypanosoma cruzi*, and erythroblastosis fetalis. The clinical presentation of acute toxoplasmic retinochoroiditis can be indistinguishable from uveitis associated with syphilis, tuberculosis, leprosy, or sarcoidosis. CNS toxoplasmosis in immunocompromised persons may mimic other causes of enhancing

mass lesions such as lymphoma, metastatic carcinoma, tuberculoma, and brain abscesses.

### Direct Detection and Isolation of Parasites

*Toxoplasma* may be demonstrated on stained specimens of tissue, blood, amniotic fluid, and CSF.<sup>117</sup> The diagnosis of acute infection requires identification of tachyzoites, since the finding of tissue cysts does not distinguish acute from chronic infection.<sup>52</sup> Care is needed to distinguish *Toxoplasma* from other intracellular organisms such as *Histoplasma*, *Trypanosoma cruzi*, *Sarcocystis*, and *Leishmania*. Tachyzoites may be difficult to find in tissue sections stained with hematoxylin and eosin or other routine stains, and special techniques such as direct immunofluorescence or the peroxidase-antiperoxidase method may be necessary for their detection.<sup>117,118</sup> Parasites usually are not detected by microscopic examination of lymph nodes in cases of lymphadenitis, but the histopathologic changes may be sufficiently distinctive to permit a diagnosis of toxoplasmosis.<sup>52,74</sup>

Parasites may be recovered from both tissue cysts or tachyzoites in tissues and body fluids by inoculation into mice or tissue culture.<sup>52,117–119</sup> Assays based on the PCR<sup>119</sup> are extremely sensitive for the diagnosis of congenital toxoplasmosis when amniotic fluid is examined.<sup>120,121</sup> Such assays are commercially available and can also detect parasite DNA in blood,<sup>38,122</sup> CSF,<sup>123</sup> aqueous humor,<sup>124</sup> and fluid from bronchoalveolar lavage<sup>125</sup>; with variable sensitivity.

### Serologic Tests

Serologic testing remains an important means of confirming infection with *Toxoplasma*. A variety of methods are sensitive and specific for the detection of IgG antibody to *T. gondii* antigens.<sup>2,10,75,117,126–132</sup> Thus, the serologic diagnosis of toxoplasmosis acquired in the distant past is quite reliable. The Sabin-Feldman dye test detects both IgG and IgM antibody by its ability to lyse live *T. gondii* in the presence of human complement and was for many years the gold standard.<sup>10</sup> Indirect fluorescent and antibody enzyme-linked immunosorbent assay (ELISA) are sensitive tests for the detection of IgG antibody and correlate well with the dye test in adults.<sup>126</sup> Isotype-specific ELISA for IgG, IgM, IgA, and IgE; IgM capture ELISA; immunosorbent agglutination (ISAGA); and others are available from some reference laboratories.<sup>127–131</sup> Results of these tests must be interpreted with age-matched populations. The IgM capture ELISA and IgM-ISAGA are sensitive for detection of specific IgM antibodies, but titers in infants less than 6 months old are lower than in adults.<sup>129,131</sup> While a negative IgM test nearly always rules out a recently acquired infection,<sup>133</sup> a positive test is less useful because commercially available tests have been reported to generate false positive results,<sup>127,130</sup> and specific IgM antibodies may remain detectable for greater than 1 year.<sup>129</sup> Determination of the functional avidity of anti-toxoplasma IgG antibody, by its ability to withstand dissociation from antigen in chaotropic salt solution, is useful in distinguishing recently acquired antibody (low avidity) from that seen in infection more than 4 months old (high avidity).<sup>132,134,135</sup> The IgG avidity test has become important for estimating dates of infections in pregnant women, and a commercial test based on this principal is available in

Europe, but not yet in the United States. Because low-avidity results may persist for up to a year, a battery of tests including ELISA for IgM, IgA, IgE, the dye test, and differential agglutination test should be employed for interpretation of low- or equivocal avidity test results.<sup>136</sup> Direct agglutination of formalin- or acetone-fixed tachyzoites in the presence of 2-mercaptoethanol is thought to distinguish early antibodies (which react to acetone-fixed parasites) from those that develop later in infection (which react to formalin-fixed parasites).<sup>136</sup> An agglutination titer using acetone-fixed parasites that is at least one-fourth of that using formalin-fixed organisms is indicative of recent infection.

### Diagnosis of Specific Syndromes

The diagnosis of suspected acute acquired toxoplasmosis usually is confirmed by demonstrating rising titers of specific IgG antibodies or by detecting specific IgM antibodies.<sup>2</sup> A single positive IgG test does not distinguish acute from chronic infection because antibodies to *Toxoplasma* persist indefinitely after acute infection, occasionally in high titers. Detection of specific IgM antibody in newborns by IgM-ELISA or the more sensitive IgM-ISAGA indicates congenital infection, but a negative result does not exclude the diagnosis because commonly available assays lack sensitivity to detect the low-avidity IgM antibodies synthesized by young infants.<sup>2,89,129,131,137,138</sup> Infants with severe toxoplasmosis at birth in particular may have negative IgM tests; in these cases, organisms usually are detected by PCR or by smears or culture of tissue, CSF, or blood.<sup>89</sup>

Specific IgG antibodies are nearly always present in the serum of infants with congenital toxoplasmosis. Uninfected infants born to infected mothers have specific IgG antibodies because of passive transfer of maternal IgG across the placenta, but these antibodies do not persist longer than 6 to 12 months in the absence of active infection.<sup>138</sup> Examination of the pattern of bands in Western blots between mothers and infants can be used to determine specific fetal antibody production.<sup>136</sup> In active retinochoroiditis, low titers of specific IgG antibodies are usually present, but IgM antibody in the serum is not detected.<sup>93–95</sup>

Immunocompromised patients with reactivation toxoplasmosis have positive specific IgG tests and negative IgM tests.<sup>12,98</sup> While the absence of specific IgG antibodies weighs heavily against the diagnosis of active toxoplasmosis in these patients, a positive titer does not distinguish active from latent infection. For this reason, the diagnosis of CNS toxoplasmosis in AIDS patients and other severely immunocompromised patients is usually made clinically.<sup>12,98,138</sup> Persons with a suggestive clinical history, positive specific IgG test, and typical radiographic findings are given a trial of anti-*Toxoplasma* chemotherapy. In cases of toxoplasmosis, clinical and radiographic improvement is seen within 7 to 10 days. A diagnostic brain biopsy is indicated if there is failure to improve within this time.<sup>138</sup> PCR amplification of *Toxoplasma* DNA has high predictive value, but relatively low sensitivity.<sup>136</sup> Brain biopsy without an antecedent therapeutic trial is indicated for immunocompromised persons with negative specific IgG tests or nonenhancing or single lesions and those who have been receiving prophylactic trimethoprim-sulfamethoxazole, because their CNS lesions are unlikely to be due to toxoplasmosis. Positron emission tomography may help distinguish

CNS lymphoma from toxoplasmosis in persons with contrast-enhancing brain lesions.<sup>139,140</sup>

## TREATMENT

### Indications and Treatment Regimens

Most immunocompetent persons with primary toxoplasmosis do not require therapy unless there is visceral disease or persistent severe symptoms.<sup>2,141</sup> The exception is the pregnant mother, in whom early treatment may reduce the risk of fetal infection or may reduce the severity of disease if transplacental transmission has already occurred.<sup>2,34,121,142,143</sup> All children with congenital toxoplasmosis should receive treatment for 1 year.<sup>2,84,89,90,137,144</sup> Retinochoroiditis is treated for 1 to 2 weeks after resolution of symptoms with both anti-*Toxoplasma* drugs and corticosteroids to reduce inflammation.<sup>94,133</sup> The frequency of recurrent episodes of retinochoroiditis may be reduced by intermittent therapy with trimethoprim-sulfamethoxazole.<sup>145</sup> Immunosuppressed patients require therapy to control progressive disease, and therapy must be extended for the period of cell-mediated immunosuppression to prevent relapse.<sup>11,12,101,146</sup>

Most drugs for treating toxoplasmosis are active only against the tachyzoite form of the parasite, although atovaquone has activity *in vitro* against tissue cysts as well.<sup>147,148</sup> Treatment even with atovaquone as a rule does not eradicate infection. Standard therapy for most indications is the combination of the oral agent pyrimethamine and a sulfonamide, which are synergistic when given together.<sup>2,37,141,149</sup> A loading dose of pyrimethamine 200 mg over 1 day in divided doses for adults or 2 mg/kg/day for 2 to 3 days for young children is followed by a daily dose of 1 mg/kg/day for adults or every 1 to 3 days for young children.<sup>2,84,89,90,137,150</sup> In immunocompromised adults with CNS toxoplasmosis or other severe disease, pyrimethamine 75 to 100 mg/day is given for 4 to 6 weeks followed by 25 to 50 mg/day for the duration of immunosuppression.<sup>12,150,151</sup> Sulfadiazine or triple sulfonamides are preferred over other sulfonamides, which have less activity against *T. gondii*.<sup>2</sup> A loading dose of 50 to 75 mg/kg for adults or 75 to 100 mg/kg for infants is followed by daily doses of 75 to 100 mg/kg/day in four divided doses for adults or 100 to 150 mg/kg/day in four divided doses for infants. Leukovorin (folinic acid) 5 to 10 mg/day should be administered simultaneously to overcome the bone marrow-suppressive effects of pyrimethamine. Persons who receive pyrimethamine should have a peripheral blood cell and platelet count at least weekly. Clindamycin 600 mg orally or intravenously four times a day in combination with pyrimethamine has been successful in the treatment of adult AIDS patients with CNS toxoplasmosis who could not tolerate sulfonamides.<sup>151–153</sup>

Pyrimethamine is teratogenic and should not be used during the first trimester.<sup>2,34</sup> The macrolide antibiotic spiramycin (3–4 g/day in divided doses) has been used safely during pregnancy.<sup>2,34,82,142,143,154</sup> It is not as effective as pyrimethamine and sulfonamides, but appears to reduce the rate of transplacental transmission. There is no uniformly accepted treatment regimen for congenital toxoplasmosis. Some authorities recommend standard doses of pyrimethamine and sulfonamides for 1 year, while others employ lower doses of pyrimethamine or give intermittent doses of spiramycin.<sup>2,89,90,150,155</sup> Other drugs that have activity against *T. gondii* include dapsone, azithromycin,

clarithromycin, roxithromycin, atovaquone, minocycline, and rifabutin.<sup>2,141</sup>

### Maintenance and Prophylactic Therapy in Immunocompromised Persons

Following treatment of active toxoplasmosis in immunocompromised patients, suppressive therapy should be continued for the duration of immunosuppression, which often is for life.<sup>12,101,144,154,156,157</sup> The most effective regimen is the combination of pyrimethamine 25 to 50 mg/day plus sulfadiazine 2 to 4 g/day with leukovorin 5 mg/day. This regimen also affords protection against *P. jirovecii* pneumonia. Clindamycin 300 mg to 450 mg orally three times a day has been used for persons who cannot tolerate sulfonamides.<sup>12,151</sup> Prophylaxis to prevent reactivation of toxoplasmosis should be given to all HIV-infected persons who have a positive serologic test for antibodies to *T. gondii* and CD4+ T-lymphocyte counts of less than 200/ $\mu$ L.<sup>158,159</sup> The combination of trimethoprim and sulfamethoxazole is effective in the same doses used to prevent *P. jirovecii* pneumonia. The combination of dapsone 50 mg/day plus pyrimethamine 50 mg/week with leukovorin 10 mg/week<sup>157</sup> or atovaquone 750 mg of suspension twice a day,<sup>154</sup> is an alternative for persons who cannot tolerate sulfonamides. The efficacy of azithromycin in preventing reactivation of toxoplasmosis is under study.<sup>2,141</sup> Suppressive therapy or prophylaxis for toxoplasmosis in HIV-infected patients can be safely withdrawn when the CD4+ T-lymphocyte counts has returned to greater than 200/ $\mu$ L and the HIV viral load has remained low for 6 months.<sup>160</sup>

### Management of Acute Toxoplasmosis During Pregnancy

A strategy for the management of toxoplasmosis acquired by the pregnant woman has been outlined by French investigators.<sup>2,121,132,143</sup> When the diagnosis of acute toxoplasmosis is suspected, the mother receives spiramycin 1 g orally three or four times a day while awaiting results of confirmatory serologic tests. The purpose of spiramycin is to prevent fetal infection if this has not yet occurred. If the confirmatory studies indicate that infection may have been acquired after conception, an amniocentesis is performed as soon as possible at 17 weeks or later. Amniotic fluid is examined by a sensitive and specific PCR-based assay for *Toxoplasma*.<sup>121</sup> A positive assay confirms fetal infection, in which case one option is to terminate the pregnancy depending on the stage of gestation and the parents' wishes. If infection appears to have occurred late in pregnancy or if the parents wish to continue the pregnancy, pyrimethamine, sulfadiazine, and leukovorin are given until term. If the PCR assay is negative, the fetus is considered to be uninfected, and spiramycin is continued until delivery. The pregnancy is monitored closely with periodic fetal ultrasonography, and the amniocentesis is repeated if there is suspicion that fetal infection has occurred. The newborn is tested for infection at the time of delivery and treated aggressively if congenital toxoplasmosis is detected. This strategy has been shown to be effective in lowering the rate of severe congenital toxoplasmosis by identifying infections that occur early in pregnancy and that would have devastating consequences if the pregnancy

were continued.<sup>121,142,143</sup> It is controversial whether it has otherwise achieved a significant reduction in the overall numbers of cases of congenital toxoplasmosis by reducing the rate of transplacental transmission when compared with historical data.<sup>161,162</sup> By identifying pregnancies in which transmission from the mother to the fetus has not occurred, it also has eliminated the need for considering termination of pregnancy on every occasion of acute maternal infection. In effect, it has spared as many as seven or eight uninfected fetuses from the possibility of therapeutic abortion for every fetus that is infected.

Variations of this strategy are practiced in countries of Europe where rates of maternal infection are high and the infrastructure exists for antenatal serologic screening of pregnant mothers to detect new infections as well as the laboratory expertise to perform accurate examination of amniotic fluid specimens. In countries such as the United States, where rates of acute maternal infection are low, this strategy is not uniformly practiced, and there is ongoing debate about its cost-effectiveness.<sup>163–166</sup> In several states, newborn screening for IgM antibodies to *T. gondii* is practiced to identify subclinical as well as symptomatic congenital infections soon after birth so that treatment can be given in a timely fashion to lower the risk of adverse sequelae.<sup>50,89,131</sup> It is not known, however, whether postnatal treatment is effective, because controlled trials have not been carried out.<sup>167</sup> In developing countries, where rates of maternal infections are high, the costs of antenatal screening and diagnosis or newborn screening and treatment are prohibitive.

## PREVENTION AND CONTROL

Several studies have shown the efficacy of educational efforts to teach techniques for avoidance of acquisition of toxoplasmosis.<sup>168,169</sup> Seronegative pregnant women or immunocompromised persons should not be exposed to cat feces either in the setting of litter boxes or by digging in soils where cats have defecated.<sup>170,171</sup> Hands should be washed after contact with potentially contaminated soil or meat that may contain tissue cysts. Meat should be thoroughly cooked. In light of recent suggestions that dogs that roll in cat feces may carry infectious oocysts, pet grooming may be a risk factor for transmission.

One strategy for preventing human toxoplasmosis is to reduce the bradyzoite load in food animals. A commercial live vaccine is available in New Zealand and the European Union which reduces the incidence of *Toxoplasma*-induced abortion in sheep, and may reduce the load of parasites in herds under certain management schemes.<sup>172</sup> There is some evidence that careful husbandry practices in swine lower *Toxoplasma* burdens, including cooking feeds and excluding cats from farms.<sup>3,5,170</sup> A vaccine for cats that prevents oocyst shedding has been developed and tested, but is not commercially available.<sup>173</sup> Should it be marketed, it is not expected to have a major impact on the epidemiology of disease, but could be recommended in situations where cat owners are willing to pay to lower the risk of cat transmission. No human vaccine is available or near development.

# Filariasis

THOMAS B. NUTMAN  
JAMES W. KAZURA

## INTRODUCTION

Lymphatic filariasis is caused by infection with any of three closely related parasitic nematodes—*Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori*. Unlike most other helminthiases endemic in tropical areas of the world, the burden of infection and disease in lymphatic filariasis occurs primarily during adulthood and not childhood or infancy. The greater impact of lymphatic filariasis on older age groups is due to the inefficiency of transmission by the obligatory arthropod vector and the fact that infection burdens are determined by the chronicity and intensity of exposure to infective stages of the organisms, which do not multiply in the mammalian host.

Because disease due to lymphatic filariasis is characterized by disfigurement of the limbs (elephantiasis) and genitalia (hydroceles and other anatomical changes in the male genitalia), it is often perceived as having adverse economic and psychosexual effects as well as medical consequences. This is particularly evident in the developing countries of the tropics where physical labor is still the major means of earning money. According to some estimates, lymphatic filariasis is among the leading health-related impediments to economic and social development in economically disadvantaged areas of the tropics.<sup>1</sup>

Lymphatic filariasis can be transmitted in any region of the world where the appropriate mosquito vector breeds. It currently is a significant health problem in tropical Africa, Asia, and the Indian subcontinent, many islands of the western and southern Pacific, and focal areas of Latin America. The infection was endemic in the southern United States and Japan in the 19th and first half of the 20th century, but disappeared as breeding sites diminished with development of modern water drainage and sewage systems. In the tropics, the geographic distribution of *W. bancrofti* and *B. malayi* infections is expanding due to increased numbers of breeding sites that appear when large numbers of people migrate from rural areas to urban slums. These pessimistic epidemiologic trends contrast the recently realized appreciation that it may be possible to eradicate lymphatic filariasis by using currently available chemotherapies in a cost-effective manner.<sup>2</sup>

## I. NEMATODE INFECTIONS

### AGENTS

The existence of lymphatic filariasis has been recorded in ancient Chinese, Indian, Persian, and Arabic writings, but the causative agents and their life cycles were not described in detail until the late 19th century.<sup>3,4</sup> The microfilariae of *W. bancrofti*, first discovered by Demarquay in hydrocele fluid from a patient in Cuba in 1863,<sup>5</sup> were later identified in the urine by Wucherer in 1868<sup>6</sup> and in the blood by Lewis in 1872.<sup>7</sup> Manson described the periodicity of microfilariae in the peripheral blood<sup>8</sup> and also demonstrated that mosquitoes transmit the parasite.<sup>9</sup> Bancroft was the first to describe the adult female worm<sup>10</sup> and the adult male worm was later described by Bourne.<sup>11</sup> Bancroft in 1899<sup>12</sup> and Low in 1900<sup>13</sup> established the mode of transmission of the parasite. Lichenstein, Brug, and Buckley were primarily responsible for the identification of the brugian parasites.<sup>14</sup>

*W. bancrofti*, *B. malayi*, and *B. timori* are threadlike nematodes having five morphologically and biochemically distinct stages in their life cycle. Infective or third-stage larvae are transmitted to humans during blood feeding by mosquitoes. The organisms are deposited from the mouth parts of the mosquito in the vicinity of the skin puncture wound, and within several minutes make their way through the dermis to enter the local lymphatics. Several hours later, infective larvae shed their cuticle and develop a new surface (a process referred to as molting) that presents novel antigens and other molecules to the mammalian host. These fourth-stage larvae migrate centrally in lymphatic vessels and over a period of approximately 9 months develop into sexually mature adult male or female worms. Adult worms are considerably larger than larval stages (male worms are 20–40 mm in length, and female worms 40–100 mm) and have highly differentiated and complex reproductive and digestive systems. This stage of the parasite dwells primarily in the afferent lymphatics. Although all of the anatomical areas in which adult lymphatic filariae live in humans are not known with certainty, large numbers are present in the lymphatics of the lower extremities (inguinal and obturator groups), upper extremities (axillary lymph nodes), and, for *W. bancrofti*, male genitalia (epididymis, spermatic cord, testicle). Based on observations of inflammatory reactions elicited by administration of drugs that kill adult worms, it is likely that adult filariae are distributed in subcutaneous tissues more than several centimeters distant from major lymph node groups. The mean reproductive life span of adult worms is approximately 5 years.

Following copulation with male worms, fecund female parasites release large numbers (often more than 10,000 per day) of embryonic forms or first-stage larvae. These parasites are referred to as microfilariae, which distinguish their small size compared with the larger adult worm (the former are 260 µm in length and approximately 10 µm in width). Microfilariae of lymphatic filariae differ from those of other filarial nematodes that infect humans in several ways. First, *W. bancrofti* and *Brugia* microfilariae are enclosed by an acellular sheath. This chitin-containing structure is a remnant of the embryonic eggshell or vitelline membrane and is not present in microfilariae of *Onchocerca volvulus* or *Loa loa*. Microfilariae of

*W. bancrofti* and *B. malayi* differ morphologically from each other in the pattern of nuclei in the cephalic and caudal regions. Second, after their release from female worms, microfilariae enter the blood (presumably by passage through the thoracic duct), where they circulate in large numbers. In many endemic areas, it is not unusual for the blood of an infected person to contain more than 10,000 microfilariae per milliliter. Third, *W. bancrofti* and *Brugia* microfilariae frequently have a nocturnal periodicity whereby large numbers of the organisms are present in the peripheral circulation between midnight and 6 AM with few or none present in the circulation during the day. When absent from the peripheral circulation, microfilariae are sequestered in deep vascular beds of the lung and other organs. This peculiar behavior appears to be an example of adaptation to local ecological conditions in that the time at which peak parasitemia occurs coincides with the time when the local mosquito vectors take their blood meal.<sup>15</sup> In most areas of the world, this occurs during the night hours. The mechanisms that regulate microfilarial periodicity in humans are poorly understood, though the lower pH present in the

pulmonary venous circulation during sleep is thought to play a role in migration of the parasites from this site.

After ingestion in a blood meal taken by a female mosquito, microfilariae exsheath within 24 hours, penetrate the chitinous gut wall of the mosquito, and migrate into the thoracic musculature. Over a period of 10 days to 2 weeks, the organisms mature to become third-stage larvae capable of infecting another human.<sup>16</sup> The nature of the relationship between filarial larvae and the local mosquito populations has a profound impact on local transmission efficiency. For example, if mosquitoes ingest unusually large numbers of microfilariae, the overall efficiency of transmission may be reduced by virtue of the fact that heavily infected mosquitoes have a shortened life span, precluding development of infective larvae. Conversely, in some mosquito-filarial interactions, there may be more efficient transmission at lower microfilarial densities, a phenomenon referred to as facilitation.

An interesting biologic feature of *W. bancrofti* and *Brugia* species relates to the fact that these nematodes carry the obligatory bacterial endosymbiont *Wolbachia*. Ultrastructure studies

\*For many filarial strains (ex. *W. bancrofti* in Africa) microfilariae become abundant in blood only at night (nocturnal periodicity), when they may be detected and spread by night-biting mosquitoes. For other strains, microfilariae are present as well by day and are spread by day-biting mosquitoes.

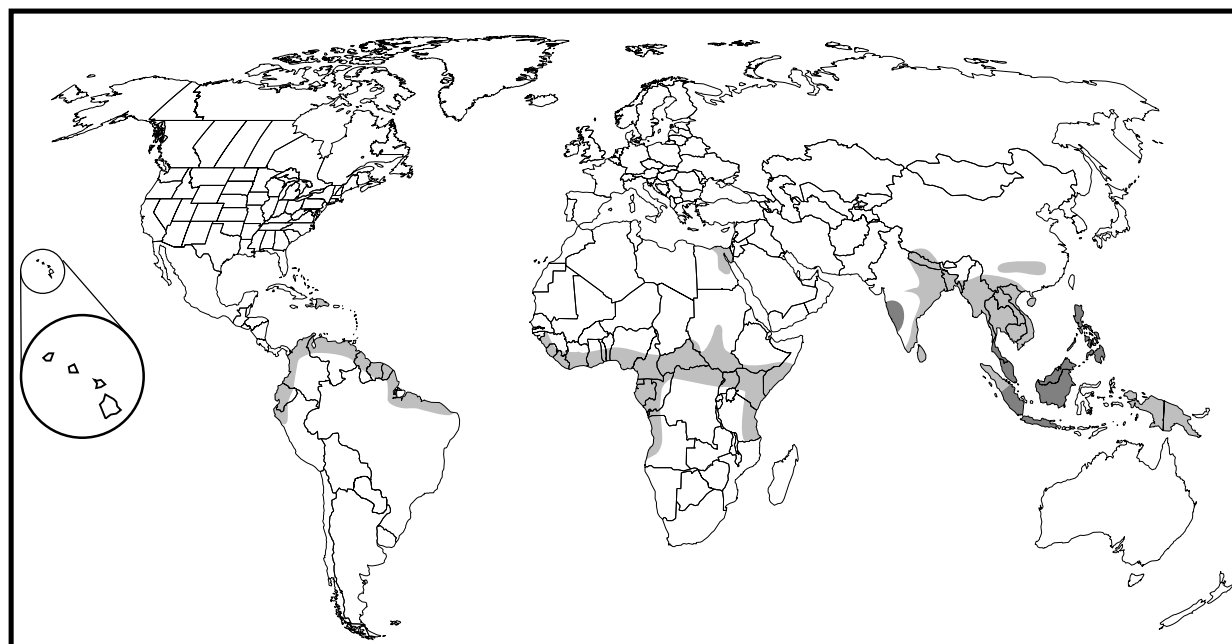

performed in the 1970s suggested the presence of intracellular bacteria in adult worms and microfilariae,<sup>17,18</sup> but it was not until the late 1990s when molecular probes and genome sequence data became available that *Wolbachia* were definitively identified in human filarial parasites.<sup>19,20</sup> These *Rickettsia*-like endosymbiotic bacteria appear to affect filariae in several ways that are pertinent to human filariasis. Incubation of *Brugia* worms with tetracycline and other antibiotics known to kill *Wolbachia* diminishes the release of microfilariae and suppresses larval molting, suggesting that the bacteria are involved in embryogenesis and regulation of the parasite life cycle.<sup>21,22</sup> In the context of human lymphatic filariasis, administration of doxycycline to persons with *W. bancrofti* infection prior to the microfilaricidal drug ivermectin has been observed to augment the suppression of microfilaremia.<sup>23</sup> In addition, acute post-treatment febrile reactions in patients with *B. malayi* infection given diethylcarbamazine have been correlated with presence of *Wolbachia* and pro-inflammatory cytokines in the blood,<sup>24</sup> consistent with the notion that *Wolbachia*-derived molecules with the property of bacterial endotoxins are released by dying worms and initiate inflammatory responses mediated by innate immune pathways.<sup>25</sup> Taken together, these findings raise the possibility that antibiotics directed against *Wolbachia* might be useful in efforts aimed at controlling and treating lymphatic filariasis (see later discussion). There is a need, however, to identify anti-*Wolbachia* agents that can be given for short periods of time (doxycycline was administered daily for 6 weeks prior to ivermectin in the study cited previously) and with broader applicability than the tetracycline antibiotics, which cannot be given to pregnant women or young children because of their effect on dentition and bone growth.

## EPIDEMIOLOGY

It is estimated that 120 million people worldwide are infected with one of the three genera of lymphatic filariae.<sup>26,27</sup> More than 90% of infections are due to *W. bancrofti* and, of these, the greatest number of infected persons live in sub-Saharan Africa, Southeast Asia, and the western Pacific. The infection is prevalent in India, Indonesia, the Philippines, Papua New Guinea, and several Pacific countries, such as parts of Fiji and Tahiti. Up until the last decade or so, there were also more than 20 to 30 million cases in China. Bancroftian filariasis is also a significant public health problem in many countries of equatorial East Africa (e.g., Kenya and Tanzania) and West Africa (e.g., Nigeria and Ghana). Within Africa, *W. bancrofti* infection is not limited to these tropical zones since endemic foci are found as far north as the Nile delta in Egypt and Sudan. The prevalence of bancroftian filariasis has decreased markedly over the past few decades in Latin America. Endemic foci persist in several islands in the Caribbean (Haiti, Dominican Republic, Trinidad and Tobago) and coastal areas of South America (Brazil, Guyana, Suriname). There are no animal reservoirs of *W. bancrofti*.

Infection with *B. malayi* is limited to Asia (China, India, and Malaysia) and several Pacific island groups (e.g., Indonesia and the Philippines). There are fewer than 10 to 20 million persons in these areas infected with *B. malayi*, which may coexist with *W. bancrofti*. *B. malayi* infection is a zoonosis in that there are feline and primate reservoirs. *B. timori* infection is limited in its distribution to the islands of southeastern Indonesia.

Within a given geographic area, the distribution of lymphatic filariasis is highly focal such that the frequency of

### Lymphatic Filariasis

■ *Wuchereria bancrofti*

■ *Wuchereria bancrofti* and *Brugia malayi*

Note: *Brugia timori* is limited to the Timor Island of Indonesia

infection in some communities is high compared with physically approximate localities. This heterogeneity of infection patterns, both at the local level and globally, is due in large part to the peculiarities of the ecological relationships between the mosquito vector, the human host, and the impact of filarial parasites on both. Unlike other common vector-borne infectious diseases of the tropics (e.g., malaria), several genera of mosquitoes are capable of transmitting lymphatic filariae. *W. bancrofti* is transmitted in many rural areas of Africa and the Pacific by *Anopheles* species.<sup>28</sup> The proximity of human dwellings to breeding sites increases the risk of repeated contact with mosquitoes bearing infective larvae. In many urban areas of the world, including India, *Culex* species is the major vector of *W. bancrofti* and *B. malayi*.<sup>29</sup> Unlike anopheline mosquitoes, larvae of these mosquitoes breed readily in small pools of water that form in discarded tires and cans. Other vectors include *Aedes aegypti* in some Pacific islands (e.g., Tahiti) and *Mansonia*, which transmits only *B. malayi*. These various genera of mosquitoes also differ in their efficiency of transmission. In general, anopheline mosquitoes are less efficient vectors of *W. bancrofti* than are culicine mosquitoes.

The age-related pattern of infection, as judged by the proportion of persons harboring microfilariae in the blood (the "microfilarial carrier rate," see later discussion), increases gradually with age up until the third or fourth decade of life, after which it remains constant or slightly decreases. This epidemiologic pattern is related to the gradual slow accumulation of adult-stage worms over time. The proportion of the entire population or a specific age group with patent infection is remarkably variable in different endemic areas. For example, the overall microfilarial carrier rates are approximately 10% in the Nile delta, 20% to 40% in parts of East Africa, and often greater than 60% in Papua New Guinea.

In addition to these differences in infection patterns, there is remarkable variation in the frequency of various disease manifestations according to age and geographic area. Lymphatic disease, manifest by persistent lymphedema of the lower extremity or genital disease in males (see later discussion), is rare in persons less than 10 years of age, and tends to increase gradually throughout life. Of the total 120 million persons estimated to be infected in all endemic areas, about one-third have some clinically overt disease. The likelihood of developing such manifestations appears to be particularly high in some areas of the world, such as India, Pacific islands such as Papua New Guinea, and equatorial Africa, whereas it is considerably lower in the Caribbean and South America. Systematic epidemiologic studies using uniform criteria for clinical diagnosis and unbiased samples of populations at risk of lymphatic disease have not, however, been performed in most endemic areas.

Recent studies have demonstrated that the local transmission conditions account in part for the striking heterogeneity of disease manifestations that may be observed within a given geographic area. In some areas of Papua New Guinea, for example, the prevalence of lymphedema of the lower extremities may vary from less than 5% to 15% in villages within 10 km of each other. Hydrocele rates in men over the age of 20 years also range from less than 1% to over 20% in geographically approximate sites.<sup>30</sup> Based on the fact that there is a positive correlation between the intensity of transmission<sup>30</sup>

and disease, it is likely that cumulative exposure to infective larvae is an important risk factor for lymphatic pathology at the population level.

## DISEASES

Infection with *W. bancrofti*, *B. malayi*, or *B. timori* can cause a wide variety of clinical manifestations, ranging from those without apparent clinical disease to those with lymphedema and/or severe disfigurement of the limbs and genitalia. From the clinical perspective, it should be stressed that there is a great deal of overlap in these symptom complexes, several of which may occur contemporaneously, and an individual may manifest each at different times during his or her lifetime.

### Subclinical Patent Infection

The overwhelming majority of filarial-infected inhabitants in endemic areas have few overt clinical manifestations of their filarial infection despite large numbers of circulating microfilariae in the peripheral blood.<sup>31</sup> Although they may be clinically asymptomatic, virtually all persons with patent *W. bancrofti* or *B. malayi* infection (microfilaria- and/or circulating filarial antigen-positive) have some degree of subclinical disease that includes microscopic hematuria and/or proteinuria,<sup>32</sup> dilated (and tortuous) lymphatics (visualized by lymphoscintigraphy<sup>33–35</sup>), and—in men with *W. bancrofti* infection—scrotal lymphangiectasia (detectable by ultrasound).<sup>36–38</sup>

Moreover, population-based studies of the relationship between microfilarial carrier rates and the frequency of lymphatic disease (see later discussion) indicate that microfilaremia per se is not more common among clinically asymptomatic persons compared with those with disease.<sup>39</sup> Both of these findings suggest that patent infection is not necessarily a clinically benign condition.

### Acute Adenolymphangitis

Acute adenolymphangitis (ADL) is often the first manifestation of lymphatic filariasis, which appears during adolescence. It is characterized by the sudden onset of high fever, painful lymph node and lymphatic inflammation (lymphangitis and lymphadenitis), and transient local edema. The lymphangitis is retrograde, extending peripherally from the lymph node draining the area where the adult parasites reside—the retrograde nature of the lymphadenitis distinguishes filarial-induced disease from bacterial-induced lymphangitis. Regional lymph nodes (e.g., inguinal, obdurator, axillary, epitrochlear) are often enlarged, and the entire lymphatic channel can become indurated and inflamed. Concomitant local thrombophlebitis can occur as well. In brugian filariasis, a single local abscess may form along the involved lymphatic tract and subsequently rupture to the surface. The lymphadenitis and lymphangitis can involve both the upper and lower extremities in both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection. This genital involvement can be manifested by funiculitis, epididymitis, scrotal pain, and tenderness.

In previously asymptomatic persons, the typical episode has a duration of 4 days to approximately 1 week, and may

recur one to three times per year.<sup>40</sup> Episodes of ADL tend to be more severe and of longer duration in persons with preexisting lymphatic disease of the affected extremity.<sup>40</sup>

In endemic areas, another type of acute disease—dermatolymphangioadenitis (DLA)—is recognized as a syndrome that includes high fever, chills, myalgias, and headache. Edematous inflammatory plaques clearly demarcated from normal skin are seen. Vesicles, ulcers, and hyperpigmentation may also be noted. There is often a history of trauma, burns, radiation, insect bites, punctiform lesions, or chemical injury. Entry lesions, especially in the interdigital area, are common. DLA is often diagnosed as cellulitis.

### Filarial Fever

Persons with filarial infection may present with an acute self-limited episode of fever in the absence of obvious inflammation of the lymphatics as described previously. These “filarial fevers” may be confused with other febrile illnesses, particularly malaria, and are often diagnosed on the basis of an appropriate epidemiologic history (i.e., chronic exposure to mosquitoes bearing infective larvae) and laboratory findings supportive of the diagnosis (see later discussion).

### Lymphedema of the Arms, Legs, and Breasts

Swelling of the upper or lower extremities is the most common chronic manifestation of lymphatic filarial infection. Disease of the lower extremities is more prevalent.

Leg involvement in bancroftian filariasis may include the entire limb, whereas only the area below the knee is usually involved in brugian filariasis. The World Health Organization has developed a grading system to quantify the severity of involvement.<sup>41</sup> Grade I indicates pitting edema that is reversible upon elevation of the leg; grade II, nonpitting edema that does not resolve with elevation of the extremity; and grade III, an increase in the degree of swelling compared with grade II, and sclerosis with papillomatous changes in the skin. Grades II and III lymphedema are commonly referred to as elephantiasis (Fig. 98-1). Although both lower extremities may be involved, asymmetrical involvement is the rule.

In some persons with filarial-associated edema, the overlying skin may exude serous fluid suggestive of lymph. Although it is possible that this sign occurs as a result of increased hydrostatic pressure in the lymphatics draining the skin, skin turgor alone cannot reliably be used to distinguish between edema due to lymphatic disease and that from other causes, such as cardiac failure and liver disease.

Unilateral or bilateral involvement of the female breast occurs in adult residents of filarial endemic areas. This should be distinguished from chronic mastitis and other causes of chronic breast inflammation.

### Disease Involving the Genitourinary System

Along with lymphatic disease of the lower extremities, disease of the male genitalia is the most common manifestation of bancroftian filariasis. Indeed, in many endemic areas, its prevalence is greater than that of lymphedema. Genital involvement is uncommon in *Brugia* infection. The prevalence of disease of the female genitalia is not known since systematic

**FIGURE 98-1** Lymphedema of the upper and lower extremities in a 50-year-old man. Swelling had been present for approximately 10 years, and the level of microfilaremia was 1000 parasites per milliliter of blood.

surveys have not included examination of this anatomical area. Anecdotal evidence suggests that the frequency of vulvar disfigurement is low. Genital disease is usually not experienced until the teenage years. Acute painful episodes of epididymitis or funiculitis last several days and are accompanied by fever and malaise. Involvement is most commonly unilateral.

Chronic disease of the male genitals mostly produces hydroceles, which vary in diameter from less than 5 cm to over 30 cm (Fig. 98-2). As is the case with other causes of hydrocele, the scrotal contents appear translucent when transilluminated.

**FIGURE 98-2** Hydrocele and inguinal lymph node enlargement in bancroftian filariasis. The patient is a 40-year-old man who first experienced epididymitis at the age of 20. The hydrocele has been present for 2 years.

Hydroceles are usually not painful unless they are complicated by acute epididymitis or funiculitis. Thickening of the spermatic cord commonly accompanies hydroceles. The skin of the scrotum may also be thickened and have a "brawny" character on palpation. If hydrocele fluid is drained, it is clear and straw-colored. Parasites are usually not found in this fluid. Inguinal lymph nodes and other nearby lymph nodes may also be enlarged (see Fig. 98-2).

### Lymphedema of the Genitalia

Lymphedema of the genitalia involves swelling of the scrotum and/or thickened scrotal or penile skin that may have characteristic "peau d'orange" appearance.<sup>42</sup> In long-standing cases, verrucous lesions and lymphorrhea are common. The genitals may be grossly deformed and terms such as "ram horn penis" have been used to describe the gross distortion of the penis seen in this condition.

### Genital Lymphorrhea

In this condition, lymph oozes out to the exterior directly from dilated ruptured lymphatic vessels. The dermis may be normal. This frequently occurs in the scrotal wall.

### Chyluria

Patients in filarial endemic areas may occasionally pass urine with a milky appearance. Upon settling, a fatty layer separates above a clear aqueous phase. This condition results from obstruction or physiologic impairment of the renal lymphatics, with passage of lymph from the lacteals draining the genitourinary tract. Chyluria may have serious nutritional consequences in that large amounts of fat and protein are lost in the urine. Its precise frequency in filarial endemic areas has not been established, but is exceedingly low compared to lymphedema of the extremities and hydroceles.

### Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia (TPE), an asthma-like condition, is a distinct syndrome that develops in some individuals infected with either *W. bancrofti* or *B. malayi*.<sup>43,44</sup> This syndrome affects males and females at a ratio of 4-to-1, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia. The main clinical features include a history of residence in filarial endemic regions, paroxysmal cough and wheezing that are usually nocturnal (and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3000 eosinophils/mL). Chest x-rays may be normal but generally show increased bronchovascular markings; diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Total serum IgE levels (10,000 to 100,000 ng/mL) and antifilarial antibody titers are characteristically elevated.

Unlike many subjects with lymphatic filariasis, those with TPE do not have microfilaremia. Administration of the

antifilarial drug diethylcarbamazine (see later discussion) leads to significant symptomatic improvement with commensurate decreases in eosinophilia and serum immunoglobulin E (IgE). If patients with tropical pulmonary eosinophilia are not treated appropriately, the disease may progress to chronic restrictive lung disease with interstitial fibrosis.<sup>45</sup>

### Lymphatic Filariasis in Expatriates

American servicemen returning from prolonged exposure to infectious mosquitoes in the South Pacific during World War II and French soldiers exposed in Indochina (now Vietnam) suffered from acute episodes of acute adenolymphangitis of the legs accompanied by eosinophilia. These acute disease manifestations were apparently caused by immune-mediated inflammatory responses to developing larvae and resolved on departure from the endemic area.<sup>46</sup> Progression to chronic lymphedema or elephantiasis was rare. More recent studies of Indonesian transmigrants from nonendemic to endemic regions<sup>47</sup> as well as studies in which volunteers were experimentally infected with infective larvae of *B. malayi*<sup>48</sup> provide corroboration of this process. This propensity to develop acute disease manifestations has been interpreted to be due to lack of immunological "tolerance" to filarial antigens seen commonly in those with lifelong (and early) exposure to the filarial organisms. In contrast to the preceding situation, the risk of developing acute or chronic manifestations of lymphatic filariasis for the traveler to endemic areas is extraordinarily small, given the inefficiency of transmission and the requirement for repeated contact with infected mosquitoes, although it has been seen rarely.

### PATHOGENESIS AND IMMUNOLOGY

The precise and likely multiple mechanisms leading to the diverse clinical manifestations of lymphatic filariasis have not been established. However, several factors have been suggested to underlie the development of lymphedema of the legs. Some studies suggest that lack of patent infection or amicrofilaremia is associated with elephantiasis, whereas microfilaremia is more common among clinically asymptomatic persons. Because these diverse clinical conditions correlate with differences in filarial antigen-specific T-cell responses,<sup>49</sup> it is possible that the qualitative nature of host immunity affects the pathologic sequelae of chronic infection. Second, a variety of epidemiologic, immunologic, and parasitologic observations in humans and experimental animals suggest that prenatal sensitization and the consequent immunologic tolerance to filarial antigens influences the pathologic response to infection and the propensity to development of subclinical microfilaremia during childhood.<sup>50,51</sup> Third, based on studies of immunodeficient mice experimentally infected with *Brugia*, it is probable that parasite-derived molecules directly impair lymphatic function independent of the host immune system.<sup>52</sup> Fourth, correlations between entomologic indices of transmission and patent infection and disease rates indicate that the degree of exposure to mosquitoes harboring infective larvae is a major determinant of the frequency of microfilaremia and clinical morbidity at the population level.<sup>53</sup> Fifth, preexisting lymphatic dysfunction may predispose to secondary bacterial infections

in persons who do not use footwear.<sup>54</sup> Finally, in view of the fact that susceptibility of mice to disease from a variety of helminth infections is related to the presence of genes both within and outside the major histocompatibility complex, it is possible that differences in these gene frequencies among infected persons with or without lymphatic disease is a risk factor.<sup>55–58</sup>

Establishing the relative importance of these diverse factors and a central unifying hypothesis to explain the pathogenesis of human lymphatic filariasis has been difficult because the onset of disease occurs over a period of years or decades and because of the marked heterogeneity in transmission and disease in various geographic areas. The immunological basis for the relative lack of pathology seen in the majority of individuals with patent infection, however, has been reasonably well-studied in both cross-sectional and longitudinal population-based studies; moreover, the development of circulating antigen assays to identify infected persons without microfilaremia (see next section) and measurements of multiple cytokines and chemokines have advanced our understanding of this immunologically complex filarial infection.<sup>59,60</sup> Studies in animal models and in vitro human systems have suggested that the initial immune response to infective stage larvae (L3) and to the next developmental stages (L4 and early adult stages) are dominated by pro-inflammatory and both Th1-like and Th2-like T cell responses.<sup>61,62</sup> With the onset of patency (when microfilariae appear in the blood), there is a marked diminution of the antigen-specific T cell responses (most notably T cell-derived interferon [IFN]-gamma).<sup>63–69</sup>

Clearly the inability of T cells to proliferate or produce IFN-gamma in response to parasite antigen is the hallmark of chronic, patent lymphatic filarial infection. This lack of T cell responsiveness has been shown to be primarily directed at antigen produced by microfilariae found in the circulation,<sup>70</sup> but secreted antigens from other parasite stages have been implicated as well. The mechanisms for this selective immune tolerance have been postulated to include: genetic predisposition,<sup>55,56</sup> diminished frequency of T and B cell precursors,<sup>49</sup> suppressor T cells or monocytes,<sup>71,72</sup> altered immune responses because of in utero exposure,<sup>50</sup> increased expression of downregulatory molecules like CTLA-4,<sup>73</sup> altered antigen-presenting cell function,<sup>59,74</sup> and the presence of regulatory cytokines such as interleukin (IL)-10 and transforming growth factor- $\beta$  (TGF- $\beta$ ).<sup>75</sup> Most recently, antigen reactive cells with regulatory function (e.g., classical Th2 cells, T regulatory cells, and/or IL-10 producing antigen-presenting cells) as well as antigen nonspecific T regulatory cells have been implicated as contributors to the modulating influences of pro-inflammatory responses presumably needed to induce pathology.<sup>59,76,77</sup>

Examination of protective immunity against lymphatic filariasis in human populations has been extraordinarily difficult. However, population-based studies<sup>78–80</sup> have identified groups of individuals who appear to be infection free despite long-term exposure to the filarial parasites. On balance cells from such individuals are more likely to respond immunologically to parasite antigen than were those with patent infection. Serum from these infection-free individuals has been used to identify possible vaccine candidates, only a few of which have been tested in animal models. The best evidence, however, for the induction of protective immunity has come

from studies in animals (birds, cats, ferrets) given radiation-attenuated L3 larvae; in these studies, irradiated L3s induced protection to varying degrees (from 60%–95% protection from challenge).<sup>81–84</sup> Attempts with subunit vaccines using recombinant antigens or DNA vaccination have been less successful, but for one antigen (Bm-ALT-1) levels of protection reached close to 60%.<sup>85</sup>

## DIAGNOSIS

Lymphatic filariasis is diagnosed by a combination of the appropriate epidemiologic history, physical findings, and laboratory tests. In residents of endemic areas, the appearance of lymphedema of the extremities or disease of the male genitalia is most likely due to filarial infection if the patient is older than 15 years of age and there is no other obvious cause, such as trauma to the lymphatics or congestive heart failure.

A definitive diagnosis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Examination, however, of the scrotum or the female breast using high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics.<sup>86–89</sup> Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men.<sup>86</sup> Live adult worms have a distinctive pattern of movement within the lymphatic vessels (termed the *filaria dance sign*).<sup>36,86</sup>

Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly using a giemsa-stained thin blood smear or—for greater sensitivity—after concentration of the parasites by the passage of blood through a polycarbonate cylindrical 3- to 5-mm pore filter (Nuclepore) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique).<sup>90</sup> The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region involved.

Many infected individuals do not have microfilaremia, and definitive diagnosis in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: one is an enzyme-linked immunosorbent assay (ELISA)<sup>91</sup> and the other a rapid-format immunochromatographic card test.<sup>92</sup> Both assays have sensitivities that range from 96% to 100% and specificities that approach 100%. There are currently no tests for circulating antigens in brugian filariasis.

Polymerase chain reaction (PCR)-based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed.<sup>93–98</sup> A number of studies indicate that this diagnostic method is of equivalent or greater sensitivity compared with parasitologic methods, detecting patent infection in almost all infected subjects.

Antibody-based assays for diagnosing filarial infection have typically used crude parasite extract and have suffered from poor specificity. Improvements have been made by the use of detection of antifilarial IgG4 antibodies<sup>99</sup> in that they have relatively less cross-reactivity to nonfilarial helminth antigens. Specificity has also been improved by the use of species-specific

recombinant antigens for both brugian and bancroftian infection<sup>100</sup>; indeed, a diagnostic dipstick test has been developed for use in areas endemic for brugian filariasis.<sup>101</sup>

In cases of suspected lymphatic filariasis, radionuclide lymphoscintigraphic imaging of the limbs reliably demonstrates widespread lymphatic abnormalities in both asymptomatic microfilaremic persons and those with clinical manifestations of lymphatic pathology. While of potential utility in the delineation of anatomic changes associated with infection, lymphoscintigraphy is unlikely to assume primacy in the diagnostic evaluation of individuals with suspected infection.

It is important to note, however, that it is not possible to exclude a diagnosis of filarial-induced disease in the absence of circulating antigens or parasites since disease may persist in persons with so-called burned-out infections. This situation may occur in persons who have received multiple courses of treatment or who have left endemic areas. Ancillary evidence consistent with the diagnosis of lymphatic filariasis includes peripheral blood eosinophilia, elevated serum IgE, and increased filarial-specific antibodies.

## TREATMENT AND PROGNOSIS

### Asymptomatic Lymphatic Filariasis

The optimal approach to these patients has not yet been established. However, on the basis of recent evidence demonstrating that such persons have abnormal lymphatics despite the lack of clinically overt disease, it seems advisable that a course of diethylcarbamazine be given. The drug (6 mg/kg/day) is administered two to three times daily for a total dose of 72 mg/kg body weight over a period of 10 to 14 days. In bancroftian filariasis, this results in greater than a 90% decrease in microfilaremia within one month, which persists for at least one year. The rate of lowering of *Brugia* microfilaremia is considerably slower.

Because of the possibility of acute side effects from drug therapy, such as fever, malaise, and occasionally bronchospasm (related to the release of large amounts of filarial antigens from dying parasites), the dose should ideally be limited to 3 mg/kg body weight on the first day. Fever and malaise are common in the first few days of treatment, and antipyretics such as aspirin should be given in such situations. In heavily infected patients, painful nodules in the skin, lymph node enlargement, and epididymitis may appear within a week or so of drug administration and persist for several weeks afterward. These are apparently due to inflammatory responses to dying parasites and resolve over a month or so. Management is symptomatic and should include proper hygiene to avoid secondary infections.

Recent population-based studies have established that annual single doses of diethylcarbamazine (6 mg/kg) alone or in combination with ivermectin (400 µg/kg) or albendazole (400 mg) may be as effective as a complete course in terms of lowering the level of microfilaremia.<sup>102–105</sup>

### Acute Adenolymphangitis

At present, it is recommended that a course of diethylcarbamazine be given along with analgesics. Cellulitis due to secondary bacterial infections of the lower extremities should

be treated by proper cleansing and administration of antibiotics based on results of microbiologic tests.

### Hydroceles and Elephantiasis

The optimal course for management of these conditions is not entirely clear. Drainage of hydroceles provides immediate relief, though they recur in the absence of drug therapy or surgical removal of the tunica albuginea. In the case of lymphedema of the lower extremities, it seems wise at present to administer diethylcarbamazine given the fact that the parasite load will be diminished, even though fibrosis of the lymphatics may preclude establishment of normal lymphatic drainage. In severe cases of deforming elephantiasis, surgical approaches involving lymphatic-venous and nodal-venous anastomoses have been moderately successful in diminishing the degree of leg swelling.<sup>106</sup> The long-term effects of these expert surgical techniques are under study at the present time. In all cases, it is important that the occurrence of secondary bacterial infections be kept to a minimum by practicing proper hygiene and prompt treatment of infections that do occur.

## PREVENTION AND CONTROL

Individual protection against filarial infection may be achieved by avoiding contact with infected mosquitoes. This can be done by use of bed nets, particularly those impregnated with insecticides such as permethrin. Although this approach may be useful in some circumstances, it is impractical in many areas of the world because of lack of acceptance of their use, their cost, and the fact that filarial infection is acquired over a period of 10 to 20 years. With respect to population-based approaches to control lymphatic filariasis, recent studies suggest that community-based drug therapy programs involving single annual doses of diethylcarbamazine<sup>107</sup> or table salt mixed with diethylcarbamazine<sup>54</sup> given for 4 to 6 years may be an effective means of decreasing transmission and possibly eradicating filariasis. The current strategy of the global plan to eliminate lymphatic filariasis is based on mass treatment with single annual doses of diethylcarbamazine plus albendazole or albendazole plus ivermectin for areas where onchocerciasis coexists (diethylcarbamazine is not recommended because of its potential for diminishing visual acuity in onchocerciasis).<sup>103,108</sup> Information available at the end of 2003 indicates that 122 million persons in 38 countries have thus far participated. The strategy of the global plan is being refined and guided by ongoing research aimed at understanding the ecology and transmission efficiency of the various mosquito vector species and efficacy of various drug regimens combined with insecticide-impregnated bed nets being used in malaria control programs.<sup>109</sup>

# Loiasis and Mansonella Infections

AMY D. KLION  
THOMAS B. NUTMAN

## Loiasis

### INTRODUCTION

Loiasis, infection with the filarial nematode *Loa loa*, is limited to, and highly endemic, in western and central Africa. Although generally associated with low morbidity, loiasis is the third most common reason for a medical visit in some hyperendemic regions,<sup>1</sup> and as many as 30% of long-term visitors to such areas may be infected.<sup>2</sup> Characteristic clinical features include Calabar swellings (transient localized angioedema) and subconjunctival migration of the adult parasite (eye worm). Severe manifestations of infection, including cardiomyopathy, nephropathy, and fatal encephalitis, are rare but do occur.

### AGENT

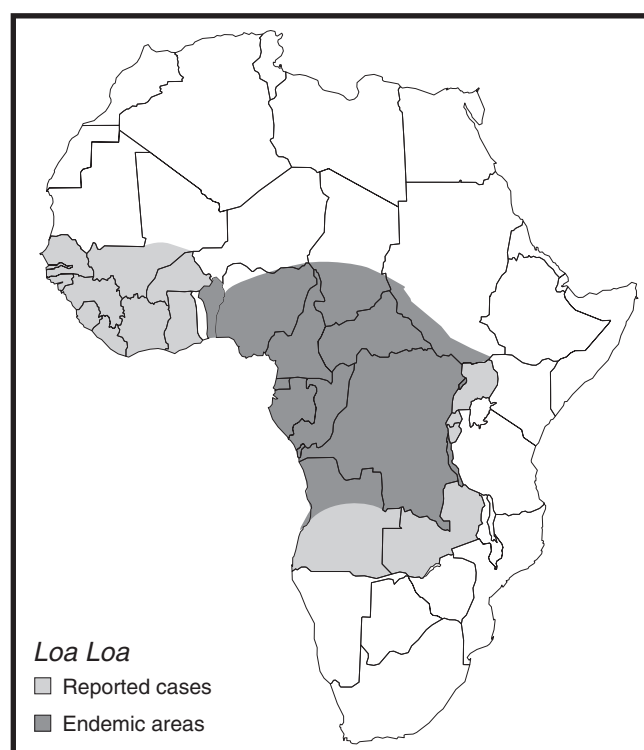

Although the extraction of an adult worm from the eye of an African slave was reported in 1770 by Mongin,<sup>3</sup> the clinical manifestations of loiasis were not described in detail until 1781 by Guyot.<sup>4</sup> The association between eye worm (synonyms: *Filaria loa*, *Filaria oculi humani*, *Filaria lacrimalis*, and *Filaria subconjunctivalis*), Calabar swellings, and *Microfilaria diurna* (Manson 1891)—a novel species of microfilaria in day blood samples of people from the Congo—remained a topic of considerable debate until the elucidation of the complete life cycle of the parasite in the early 1900s.<sup>5,6</sup>

Infective larvae are transmitted to the host by the bite of an infected female fly of the *Chrysops* species.<sup>7</sup> Over the course of 6 to 12 months, these larvae develop into white, threadlike adult worms, which migrate through the subcutaneous tissues, including those of the subconjunctiva (hence eye worm), at a rate of up to 1 cm/minute. Adult worms may live for 17 years.<sup>8</sup> In bisexual infections, microfilariae are produced and released into the bloodstream, from which they can be ingested by the vector in a blood meal to complete the cycle. Unlike the majority of filarial parasites that infect humans, *L. loa* does not appear to harbor the bacterial endosymbiont *Wolbachia*.<sup>9–11</sup>

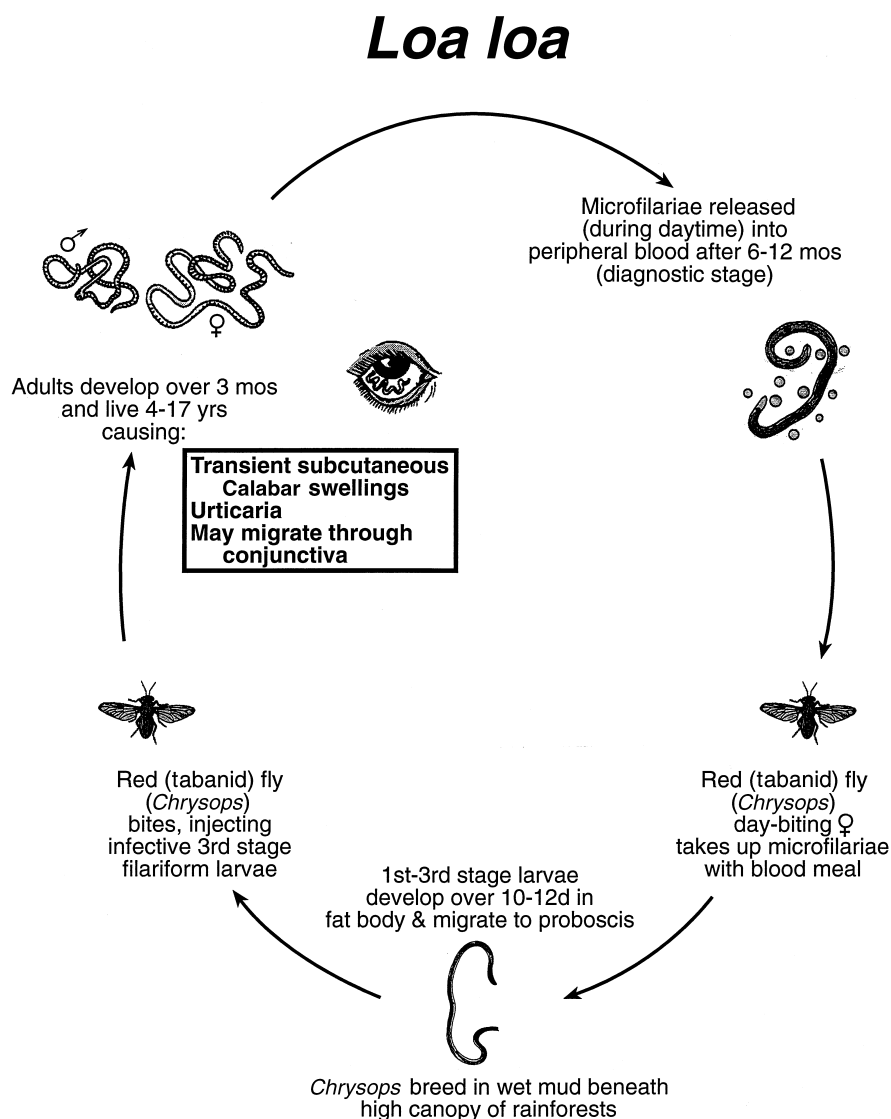

The diurnal periodicity of microfilariae in the host bloodstream coincides with the feeding pattern of the principal vectors, *Chrysops silacea* and *Chrysops dimidiata*.<sup>12</sup> These are day-biting flies that live primarily in the canopy of the rain forest.<sup>13</sup> They are attracted by movement,<sup>14</sup> dark skin and clothing, and wood smoke,<sup>15,16</sup> and they bite most frequently in shaded areas or indoors. Simian strains of *L. loa* have been described that are morphologically similar to human *L. loa*,<sup>17,18</sup> but the microfilariae demonstrate nocturnal periodicity, and infection is transmitted by night-biting *Chrysops* species that do not bite humans.<sup>19</sup> Further evidence that the human and simian parasites are distinct, yet closely related strains, includes the diurnal periodicity of blood microfilariae in non-human primates experimentally infected with human *L. loa*<sup>19</sup> and results from studies in which adult males from one strain were crossed (in mandrills) with adult females from the other, which demonstrate that the microfilarial progeny had periodicity that appeared intermediate between the parental strains.<sup>20</sup> Finally, although molecular analysis of a highly repetitive sequence showed marked conservation (99.18% identity) of the sequence between simian and human *Loa*, differences between the two strains were detected.<sup>21</sup>

### EPIDEMIOLOGY

*Loa loa* is estimated to cause chronic infection in 3 to 13 million residents of endemic areas in western and central Africa.<sup>22</sup> Distributed mainly along the coastal plains of northern Angola, southeastern Benin, Cameroon, Central African Republic, Chad, People's Republic of Congo, Equatorial Guinea, Gabon, Nigeria, Sudan, and the Democratic Republic of Congo (formerly Zaire),<sup>23,24</sup> rare cases have been reported in the region from Ghana to Guinea<sup>25,26</sup> and in Uganda,<sup>27,28</sup> Mali,<sup>29</sup>

Zambia,<sup>23,30</sup> and Ethiopia.<sup>31</sup> The occurrence of *L. loa*-related encephalopathy following mass treatment of onchocerciasis has led to renewed interest in mapping the distribution of loiasis in Africa and subsequently to the development of a number of new epidemiologic techniques, including remote sensing for suitable habitats for *Chrysops* sp.<sup>32</sup> and RAPLOA, a rapid assessment method to determine the proportion of community members with a history of eye worm.<sup>33</sup> However, the utility of these techniques in providing a better geographic map of *L. loa* endemicity remains to be seen.<sup>34</sup>

Most infected people have a history of prolonged exposure (more than 4 months' residence in an endemic area),<sup>35</sup> although cases have been reported in people after repeated short stays<sup>36</sup> and anecdotally after 1 or 2 weeks of intense exposure. In hyperendemic areas, exposure as defined by the presence of filaria-specific antibodies may approach 100%,<sup>37</sup> and up to 40% of the population may be clinically infected (i.e., have clinical symptoms or detectable blood-borne microfilariae).<sup>1</sup> Although nonhuman primates can be experimentally infected with *L. loa*, natural infection appears to be restricted to humans.<sup>38</sup>

Alterations in the ecology of the rain forest, primarily due to rubber plantations, which have a lower canopy and scant undergrowth, have led to an increased prevalence of loiasis in some regions.<sup>39</sup> Conversely, village development with replacement of forest with farmland may decrease transmission by reducing the vector population.<sup>40</sup> The need for both a reservoir of infected people and conditions that support the insect vector is illustrated by the lack of establishment of endemic foci of loiasis in Cameroon following immigration of a large number of microfilaremic people to a nonendemic region<sup>41</sup> or in Louisiana, where *Chrysops* vectors capable of transmission of loiasis to humans exist<sup>42</sup> but microfilaremic individuals are exceedingly rare.

## DISEASE

Whereas the majority of infected people from endemic areas are asymptomatic despite high levels of microfilariae detectable in the peripheral blood, visitors to endemic areas tend to be symptomatic, with a predominance of "allergic symptoms," including pruritus, urticaria, and transient, migratory

**FIGURE 99-1** Calabar swelling of the right hand.

angioedema, or Calabar swellings.<sup>35,43</sup> Clinical complications, with the exception of renal abnormalities, are also more common in nonendemic patients, in whom circulating microfilariae are rarely detectable. Characteristic laboratory abnormalities in loiasis include eosinophilia (often in excess of 3000/ $\mu$ L) and elevated serum IgE, both of which are more pronounced in symptomatic patients without detectable microfilariae in the blood.

### Calabar Swellings

Calabar swellings (Fig. 99-1) may occur anywhere on the body but are most common on the face and extremities, and they may occur following local trauma. These are evanescent and migratory angioedematous swellings. The edema is often preceded by local pain or itching lasting 1 or 2 hours, after which a 10- to 20-cm nonerythematous, nonpitting swelling develops. The swelling generally resolves in 2 to 4 days, but it may last as long as several weeks. Recurrences are common at the same site, but swellings may develop anywhere on the body. The precise cause of Calabar swellings remains unproven, although they are thought to represent hypersensitivity responses to antigens or microfilariae released by the adult parasite as it migrates.

### Eye Worm

Migration of the adult worm across the conjunctiva, eye worm, occurs with equal frequency in natives of and visitors to endemic areas<sup>43</sup> (Fig. 99-2). Although this migration is often associated with a transient intense edematous conjunctivitis, most episodes resolve without sequelae.

### Complications

Renal involvement, as defined by hematuria or proteinuria, occurs in up to 30% of infected people and may be transiently exacerbated by treatment.<sup>35,43,44</sup> Proposed mechanisms for these findings include immune complex glomerulonephritis or mechanical trauma due to the filtration of large

**FIGURE 99-2** Subconjunctival migration of an adult *Loa loa*. (From Armed Forces Institute of Pathology.)

numbers of blood-borne microfilariae,<sup>44-47</sup> although microfilariae are rarely seen in the urine.<sup>46,48</sup> Azotemia or progression to renal failure is uncommon.

Unusual prior to the introduction of diethylcarbamazine in 1947, encephalitis is certainly the most serious complication of *L. loa* infection.<sup>49</sup> It is most common in people with high levels of microfilaremia (>5000 microfilariae/mL of blood) (Fig. 99-3) and is associated with the presence of microfilariae in the cerebrospinal fluid.<sup>50,51</sup> Symptoms may range from headache, irritability, and insomnia to coma and death. In fatal cases, autopsies have demonstrated generalized acute cerebral edema or encephalitis with necrotizing granulomas around degenerating microfilariae.<sup>49</sup> Mass distribution of ivermectin in areas where *L. loa* and *Onchocerca volvulus* are coendemic has revealed similar posttreatment central nervous system (CNS) effects.<sup>47,52</sup> Although the mechanism underlying these neurologic sequelae of ivermectin treatment remains unclear,<sup>53</sup> hemorrhages in the palpebral conjunctiva and retina appear to be an early marker and are more frequent in the setting of high levels of *L. loa* microfilaremia.<sup>54</sup>

**FIGURE 99-3** Microfilaria of *Loa loa* in a hematoxylin-stained smear of peripheral blood. (Magnification  $\times 220$ .) (From Armed Forces Institute of Pathology.)

Other less common complications of loiasis include entrapment neuropathy,<sup>55,56</sup> psychiatric disturbances,<sup>57</sup> arthritis,<sup>58,59</sup> lymphadenitis,<sup>60</sup> hydrocele,<sup>61</sup> pleural effusion,<sup>62,63</sup> retinal artery occlusion,<sup>64</sup> posterior uveitis,<sup>65,66</sup> macular retinopathy,<sup>67</sup> blindness,<sup>68</sup> and endomyocardial fibrosis (EMF).<sup>35,69,70</sup> Circumstantial evidence linking EMF to loiasis includes their similar geographic distribution and the detection of antifilarial antibodies in some people with EMF.<sup>71</sup> Clinical resolution of biopsy-proven EMF in a nonendemic patient with loiasis following antifilarial treatment provides additional support for this association,<sup>35</sup> most likely secondary to massive reactive eosinophilia and eosinophil infiltration of the myocardium.

## Other

Microfilariae and adult worms have been detected in pathologic and cytology specimens from various unusual anatomical locations,<sup>72,73</sup> and calcified adult worms may be detected by routine radiography in some infected people.<sup>74,75</sup>

## PATHOGENESIS AND IMMUNITY

Many of the clinical manifestations of loiasis, including the characteristic Calabar swellings, are thought to be immunologically mediated and tend to be more severe in visitors to endemic areas than in the endemic population.<sup>35,43</sup> This clinical hyperresponsiveness is accompanied by hypergammaglobulinemia, marked eosinophilia, increased serum IgE levels, and a vigorous humoral and cellular immune response to filarial antigens.<sup>76</sup> In contrast, asymptomatic people tend to have high levels of circulating microfilariae and relatively suppressed immune responses to filarial antigens.<sup>43</sup> The mechanisms underlying these differences are not entirely understood but may involve genetic factors,<sup>77</sup> prenatal sensitization to filarial antigens, or differences in duration or degree of exposure to parasite antigens.<sup>78–80</sup>

The levels of parasitemia in infected people from an endemic area in Cameroon have been shown to be remarkably stable over a 1-year period.<sup>81</sup> Although the probability of being microfilaremic increased with age, age had no effect on the blood levels of microfilariae. These findings are consistent with differences in the host immune response to microfilariae among people living in an endemic area or stable differences in the dynamics of microfilarial production by individual adult worms.

As is true of most helminth infections, *L. loa* infection is characterized by eosinophilia and elevations of serum IgE, which are most pronounced in people with symptomatic infection.<sup>43</sup> The eosinophils in these patients have been shown to express surface markers associated with cellular activation, suggesting that the activated eosinophil may play a significant role in controlling the parasite number<sup>82</sup> but also may be mediating pathologic changes. The presence of peripheral blood eosinophilia has been associated with the secretion of interleukin (IL)-5 by mitogen-stimulated peripheral blood mononuclear cells (PBMCs) from patients with loiasis and other filarial infections.<sup>83</sup> Furthermore, crude or recombinant filarial antigens can induce IL-4 and IL-5 from PBMCs or CD4+ T cells in vitro.<sup>84,85</sup> Similarly, IgE can also be induced by parasite antigens in vitro and people with loiasis

have been shown to have markedly elevated numbers of B cells and T cells capable of responding to parasite antigen in vitro.<sup>85–88</sup>

The presence of long-term residents of hyperendemic areas who have neither detectable circulating microfilariae nor clinical symptoms of loiasis suggests that protective immunity to loiasis may develop in some people.<sup>89</sup> Definitive proof of naturally occurring immunity, however, will require diagnostic tests sensitive and specific enough to exclude occult infection.

## DIAGNOSIS

Loiasis should be suspected in any person returning from an endemic area who presents with urticaria, localized swellings, or visualization of an adult worm beneath the conjunctiva. It should also be considered in the differential diagnosis of eosinophilia with or without concomitant symptoms.

Definitive diagnosis is by extraction of an adult worm from the subcutaneous (or subconjunctival) space or the identification of *L. loa* microfilariae in peripheral blood. Adult male worms are approximately 3.5 × 0.5 mm and female worms are 5 to 7 × 0.3 mm.<sup>90</sup> The cuticle is thick, unstriated, and covered with irregularly spaced bosses, which are useful in identifying fragments of the worm. *Loa loa* microfilariae are approximately 290 × 7.5 μm in size and are distinguished from the microfilariae of other species (most notably *Wucheria bancrofti*, *Brugia malayi*, and *Mansonella perstans*) by their diurnal periodicity, sheath, and the presence of three or more terminal nuclei.<sup>23</sup> Of note, the periodicity of *L. loa* microfilariae is affected by differing time zones and by variations in body temperature,<sup>91</sup> supporting the hypothesis that blood microfilarial levels are linked to the circadian rhythm of the host. These factors must be taken into account when determining the optimal time of blood sampling.

Serology may be useful for confirming the diagnosis of filariasis in visitors to endemic areas who have suggestive clinical symptoms or unexplained eosinophilia; however, available methods using crude antigen extracts from *Brugia* or *Dirofilaria* species do not differentiate between *L. loa* and other filarial pathogens.<sup>92,93</sup> The utility of such testing in endemic areas is limited by the presence of antifilarial antibodies in up to 95% of the population in some areas.<sup>37</sup>

In a small study of patients with parasitologically proven loiasis and/or *M. perstans* infection living in an endemic area, a detectable IgG4 response to *L. loa* adult antigen was 92% sensitive and 94% specific for *L. loa* infection.<sup>94</sup> Cross-reactivity in patients with onchocerciasis and lymphatic filariasis was not assessed, however. Furthermore, the difficulty in obtaining adult *L. loa* worms will likely limit the widespread use of serologic tests based on crude extracts of *Loa* antigens. Recently, an IgG4 enzyme-linked immunosorbent assay using a recombinant antigen has been shown to be highly specific (98%) but less sensitive (56%) in detecting *L. loa* infection.<sup>95</sup>

The identification of *Loa*-specific DNA sequences that are present in the parasites' genome, often in multiple copies,<sup>96,97</sup> has enabled the development of polymerase chain reaction (PCR)-based strategies for both speciation of *L. loa* from pathologic specimens difficult to identify on morphologic grounds and sensitive diagnostic strategies. Using a series of two to four different (but each *Loa*-specific) targeted

sequences, a PCR-based multiplex technique has been developed that appears to be approximately 10 times more sensitive than traditional blood filtration. Furthermore, a colorimetric detection system that can be performed at ambient temperature has simplified the readout, permitting its use in endemic areas.<sup>98</sup>

The differential diagnosis of Calabar swellings includes angioedema associated with C1 inhibitor deficiency, infection with other filariae (particularly *M. perstans* and *O. volvulus*), nematode and trematode infections (e.g., trichinellosis and gnathostomiasis), and hypereosinophilic syndromes. Although “eye worm” in the setting of a compatible exposure history is extremely suggestive of loiasis, subconjunctival migration of other nematodes, including *Dirofilaria repens* (a filarial parasite of dogs and cats) and *Thelazia californiensis* (deer eye worm), has been reported.<sup>99,100</sup> Finally, the symptoms of *L. loa* infection may sometimes be difficult to distinguish from those of onchocerciasis or bancroftian filariasis, infections that may be coendemic with loiasis.

## TREATMENT AND PROGNOSIS

Diethylcarbamazine (DEC) is effective against both microfilariae and adult worms and, at a dose of 8 to 10 mg/kg/day for 21 days, remains the drug of choice for the treatment of *L. loa* infection in amicrofilaremic patients, including most long-term visitors to endemic areas.<sup>101</sup> Although it is curative after a single course in 45% to 50% of such patients, multiple courses are often necessary and recrudescence may occur up to 8 years post-treatment.<sup>102</sup> Mild side effects of treatment are common and include Calabar swellings, pruritus, arthralgias, fever, nausea, diarrhea, right upper quadrant discomfort, and a sensation of creeping under the skin.<sup>35,103</sup> Antihistamines or steroids may reduce the development and severity of these symptoms. Occasionally, mobile adult worms are seen under the skin following DEC treatment and may be removed with forceps through a small skin incision<sup>103</sup> or by excisional biopsy.<sup>104</sup>

More serious complications of the treatment of loiasis, including renal failure, shock, coma, and fatal encephalitis, are related to the microfilarial burden and may be provoked or exacerbated by the massive microfilarial lysis that occurs with DEC treatment.<sup>105,106</sup> Historically, a gradual increase in the dose of DEC and pretreatment with antihistamines and steroids have been advocated to prevent these complications; however, numerous reports have demonstrated that these interventions do not prevent encephalitis.<sup>50</sup> The exact number of microfilariae that presents a significant risk is unknown, but 2500/mL blood has been suggested. Alternatives for people with high levels of circulating microfilariae include no treatment, removal of circulating microfilariae by cytapheresis prior to DEC treatment,<sup>107,108</sup> and newer drugs, including ivermectin<sup>109–113</sup> and albendazole.<sup>114</sup>

Ivermectin, the microfilaricidal drug of choice in onchocerciasis, has been shown to reduce microfilarial levels in patients with *L. loa* infection but is ineffective against the adult worms.<sup>109,112</sup> In addition, side effects secondary to microfilarial lysis occur in 30% to 70% of patients with high levels of circulating microfilariae and, in rare cases, may be life-threatening.<sup>109,110</sup>

In uncontrolled studies, prolonged administration of high doses of the anthelmintic mebendazole has led to a decrease

in the numbers of circulating microfilariae in some patients with loiasis.<sup>115,116</sup> The frequency of adverse effects that occur because of the high doses necessary to achieve reasonable blood levels has limited its utility. Furthermore, clearance of microfilaremia is rare, and at least one study has failed to demonstrate any effect of mebendazole on *L. loa* microfilarial levels.<sup>117</sup> Albendazole, a related benzimidazole with better oral bioavailability, has been shown in a double-blind, placebo-controlled study to decrease microfilarial levels in *Loa*-infected patients when used at a dose of 200 mg twice daily for 3 weeks.<sup>114</sup> Adverse effects were not observed, even in people with more than 50,000 microfilariae per milliliter of blood. Unfortunately, shorter, higher dose regimens do not appear effective.<sup>118,119</sup> The gradual decrease in blood microfilarial levels over the course of several months suggests that albendazole may have a preferential effect on the adult parasite, explaining the lack of adverse effects associated with massive microfilarial antigen release during albendazole treatment. Sequential therapy with albendazole and a microfilaricidal agent (DEC or ivermectin) may provide an alternative to pre-treatment cytapheresis in patients with high microfilarial levels.

## PREVENTION AND CONTROL

Weekly chemoprophylaxis with diethylcarbamazine (300 mg) is effective for prevention of loiasis in long-term travelers to endemic areas.<sup>2</sup> In an uncontrolled study, monthly administration of DEC 100 mg on 3 successive days each month was also suggested as a regimen that would provide effective prophylaxis.<sup>120</sup> Vector control programs have achieved only limited success, primarily because of the dense vegetation in endemic areas and difficulties of access to the *Chrysops* breeding sites.<sup>40</sup>

## ■ *Mansonella Streptocerca*

### INTRODUCTION

Streptocerciasis, infection with the filarial nematode *M. streptocerca*, is limited to the tropical rain forests of Central Africa, although a small focus has also been found in western Uganda.<sup>121</sup> Although the infection can be completely asymptomatic, characteristic clinical features include a chronic, pruritic dermatitis and lymphadenopathy, often indistinguishable from onchocerciasis. Because adult male and female worms have been found in the skin of chimpanzees and because microfilariae have been found in gorillas, streptocerciasis may be a zoonosis.

### AGENT

Although microfilariae of *M. streptocerca* (synonyms: *Dipetalonema streptocerca* and *Tetrapetalonema streptocerca*) were first identified in 1922 in the skin of Ghanaians by Macfie and Corson,<sup>122</sup> the demonstration of adult female<sup>123</sup> and adult male worms did not occur until 1972.<sup>124</sup> Infective larvae are most likely transmitted to the host by the bite of an infected midge, *Culicoides grahamii*.<sup>125,126</sup> Over the course of months to years, these larvae develop into white, threadlike adult worms (males, 17 or 18 mm × 40 to 50 μm; females, 27 mm × 65 to 85 μm) that live in the dermal layer of the skin. In bisexual infections, microfilariae (sheathless, 2.5 to 5.0 × 180 to 240 μm) are produced and reside in the upper dermal

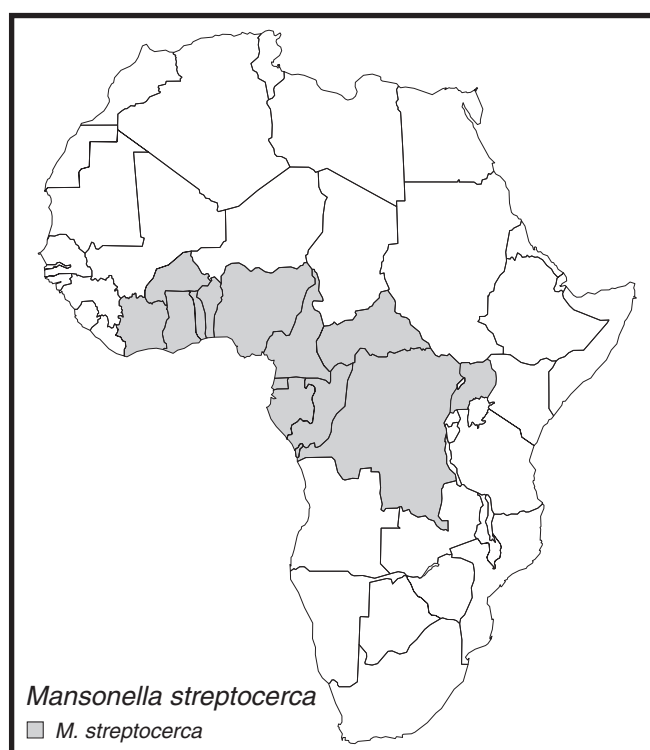

and collagen layers of the skin.<sup>127</sup> *Mansonella streptocerca* has also been found in nonhuman primates,<sup>128</sup> which appear to be additional definitive hosts for this parasite.

## EPIDEMIOLOGY

There are no good estimates of the number of residents of endemic areas in western and central Africa infected with *M. streptocerca*.<sup>23</sup> *Mansonella streptocerca* has been found in the tropical rain forests of northern Angola, Cameroon, Central African Republic, People's Republic of Congo, Equatorial Guinea, Nigeria, Uganda, and the Democratic Republic of Congo. In endemic areas, 40% of people may be infected (i.e., have clinical symptoms or detectable skin-dwelling microfilariae). Detailed analyses of the seasonality and ecology of *M. streptocerca* infection have not been performed.

## DISEASE

The major clinical manifestations of streptocerciasis are dermatologic<sup>124,127</sup> and include pruritus, papular rashes, and pigmentation changes. A chronic, pruritic dermatitis, characterized by nonanesthetic hypopigmented macules, is most common.<sup>124</sup> These macules may be discrete or confluent, and they are located predominantly over the shoulder girdle and thorax. Dermal thickening is often present. Papular eruptions occur relatively less frequently. Inguinal adenopathy is extremely common in streptocerciasis; in several studies the incidence of this finding was 100%.<sup>124</sup> Although it has been reported that massive lymphedema (elephantiasis) can occur as a result of *M. streptocerca* infection, this remains unproven. Infection is associated with peripheral blood eosinophilia without leukocytosis.<sup>124,127</sup>

## PATHOGENESIS AND IMMUNITY

Most of the pathologic changes seen in streptocerciasis are dermal and consist of sclerosis of the papillae, edema, fibrosis, and perivascular infiltration with lymphocytes and eosinophils.<sup>124,127</sup> Dermal lymphatics are also dilated. Similar to *O. volvulus* and many of the other filarial pathogens of humans, *M. streptocerca* is well adapted to the host and provokes little inflammatory reaction in the absence of treatment. With filaricidal treatment, however, inflammatory reactions do appear around adult worms and microfilariae, suggesting that the parasite is releasing antigens to which the host's inflammatory system responds.<sup>124,127</sup>

## DIAGNOSIS

Streptocerciasis should be suspected in any person returning from an endemic area who presents with pruritus, a rash, or bilateral inguinal adenopathy. Definitive diagnosis is made by the identification of *M. streptocerca* microfilariae in skin snips. These are approximately  $270 \times 5 \mu\text{m}$  in size and are distinguished from the microfilariae of other species (most notably the skin-dwelling *O. volvulus*) by a characteristic tapered hook-shaped tail (shepherd's crook) and nuclei extending to the end of the tail.<sup>124,129,130</sup> Adult worms may be found in skin biopsies, but this is extremely uncommon. *Mansonella streptocerca* DNA can be identified in skin biopsies using a nested PCR-based assay.<sup>131</sup> This approach is specific and more sensitive than skin snips for the diagnosis of streptocerciasis. There is little value in serologic evaluation for this infection.

Streptocerciasis may be confused with onchocerciasis and other chronic dermatitides. If hypopigmented macules are present, these can resemble those of lepromatous leprosy. Although the nonanesthetic nature of the nodules and their location on the upper body may suggest streptocerciasis, histopathologic evaluation is often necessary to distinguish leprosy from *M. streptocerca* infection.

## TREATMENT AND PROGNOSIS

DEC 6 mg/kg/day in divided doses for 14 to 21 days appears to be effective in killing both microfilariae and adults.<sup>124,127,132,133</sup> As in onchocerciasis, increased pruritus, urticaria, and papular eruptions along with systemic findings (arthralgias, myalgias, headaches, fever, nausea, and vomiting) may accompany treatment. Generally, these symptoms occur within 24 to 48 hours after treatment and can be treated symptomatically with antihistamines and anti-inflammatory agents. Ivermectin (150  $\mu\text{g/kg}$ ) appears to have a salutary microfilaricidal effect both in the short term (6 to 12 days)<sup>134</sup> and in the long term (1 year).<sup>135</sup>

## PREVENTION AND CONTROL

There have been no studies of chemoprophylaxis for prevention of streptocerciasis. Control programs have not been attempted, but the microfilarial suppression seen with ivermectin suggests that mass treatment campaigns for *W. bancrofti* and *O. volvulus* control may help to dampen transmission of *M. streptocerca* as well.<sup>135</sup>

## ■ *Mansonella Perstans*

### INTRODUCTION

Perstans filariasis, an infection caused by *M. perstans*, is distributed across the center of Africa, parts of North Africa, the Caribbean basin, and in northeastern South America.<sup>23</sup> Although generally associated with little morbidity, clinical manifestations may include transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis); fever; headache; arthralgias; and right upper quadrant pain. Occasionally, pericarditis and hepatitis occur.

### AGENT

The microfilariae of *M. perstans* (synonyms: *Dipetalonema perstans*, *Tetrapetalonema perstans*, and *Acanthocheilonema perstans*) were first identified in 1890 in the blood of an African with concomitant trypanosomiasis.<sup>136</sup> The adult form of *M. perstans* was first collected from the mesentery of an Amerindian in Guyana in 1898.<sup>137</sup>

Infective larvae are transmitted to the host by the bite of a number of different species of infected midges (*Culicoides* spp.).<sup>138–143</sup> Over the course of 9 to 12 months, these larvae develop into creamy-white, threadlike adult worms (males, 35 to 45 mm × 50 to 70 µm; females, 60 to 80 mm × 100 to 150 µm) that live in serous cavities—pericardial, pleural, and peritoneal—as well as in the mesentery and in the perirenal and retroperitoneal tissues. In bisexual infections, microfilariae (sheathless, 3.5 to 4.5 × 100 to 200 µm) are produced and are found in the blood without any periodicity. Like the

majority of filarial parasites that infect humans, *M. perstans* does appear to harbor the bacterial endosymbiont *Wolbachia*, although this remains a matter of controversy.<sup>10</sup>

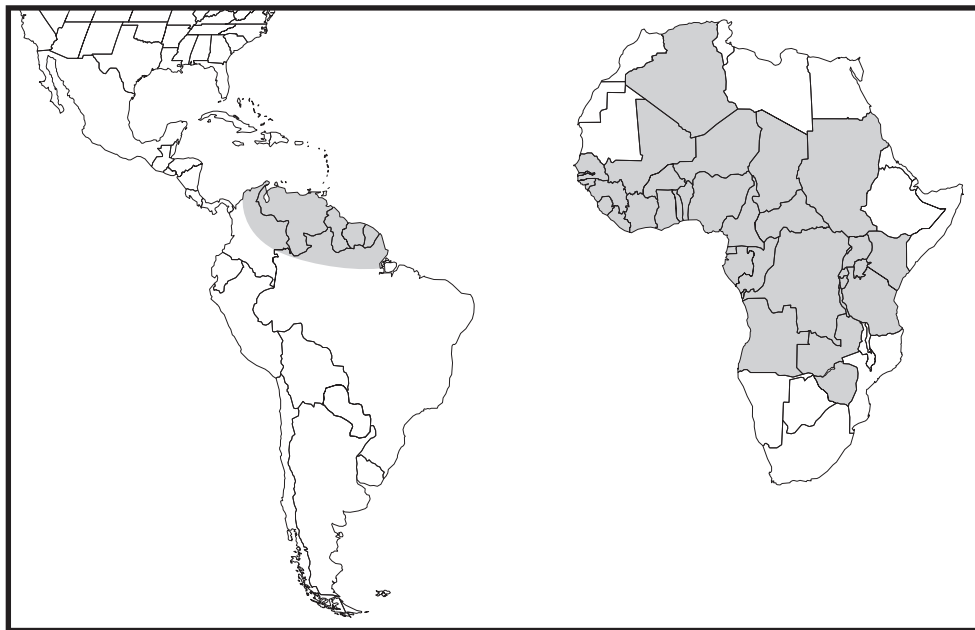

### EPIDEMIOLOGY

At least 30 million residents of endemic areas are infected with *M. perstans*.<sup>22</sup> It is distributed mainly in sub-Saharan Africa, from Senegal east to Uganda and south to Zimbabwe, and in South America along the northern coast of the entire continent, but minor foci have been identified in Tunisia and Algeria. In highly endemic areas, almost 100% of people may have circulating microfilariae. Although humans are the major reservoir of infection, nonhuman primates (gorilla<sup>144</sup> and chimpanzee<sup>128</sup>) can also be definitive hosts for the parasite.

The principal vectors of *M. perstans* are *Culicoides milnei* and *Culicoides grahamii*, but *Culicoides austeni*, *Culicoides fulvithorax*, *Culicoides kingi*, and *Culicoides furens* can also transmit infection.<sup>138–143</sup> Detailed analyses of the seasonality and ecology of *M. perstans* infection have not been performed.

### DISEASE

As with the other *Mansonella* infections, the clinical and pathologic features of this infection are poorly defined. Although most patients appear to be asymptomatic,<sup>145–148</sup> a wide range of clinical manifestations have been described,<sup>145</sup> including transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis) and recurrent urticaria.<sup>145,147,149</sup> Less commonly, fever, headache, arthralgias, and right upper quadrant pain

*Mansonella perstans*

■ *M. perstans*

can occur.<sup>145,147,149–152</sup> Pericarditis,<sup>71,153</sup> hepatitis,<sup>154–156</sup> meningoencephalitis, and neuropsychiatric disturbances<sup>145,148,156</sup> have also been reported. Rarely, conjunctival granulomata<sup>157,158</sup> and intraocular (retinal) lesions<sup>159</sup> have been seen in *M. perstans* infection.

## **PATHOGENESIS AND IMMUNITY**

The pathogenesis of symptomatic *M. perstans* infection is poorly understood. Whereas hypereosinophilia and IgE elevations are common,<sup>150,157</sup> inflammatory reactions in this infection have been difficult to document.<sup>160</sup> There is evidence that when inflammation occurs it is granulomatous.<sup>157,158</sup> Live adults induce little host response,<sup>127</sup> and pathologic findings are rare.<sup>161</sup> Occasionally, cerebrospinal fluid and urine contain microfilariae.

There have been few attempts to examine in detail the immune response to *M. perstans* infections both because of the lack of symptomatology associated with infection and because *M. perstans* is often seen in conjunction with other filarial parasites given the overlap of endemicity. Nevertheless, elevated serum IgE and peripheral blood eosinophils have been described in association with *M. perstans* infection in a number of case reports.<sup>160,162,163</sup> Although uncommon, secondary complications of hypereosinophilia due to *M. perstans* (e.g., valvular heart disease) have been reported.<sup>163</sup>

## **DIAGNOSIS**

The diagnosis is made by finding microfilariae in blood or serosal effusions. Concentration techniques may be necessary in light infections.<sup>129,164–166</sup> Rarely, adult worms may be recovered, generally as an incidental finding. *Mansonella perstans* filariasis is often associated with peripheral blood eosinophilia and antifilarial antibody elevations.<sup>150,160,167,168</sup>

## **TREATMENT AND PROGNOSIS**

Although DEC 8 to 10 mg/kg/day for 21 days remains the treatment of choice, there is little evidence that it is efficacious.<sup>147,148,151,169,170</sup> Multiple courses of therapy are often necessary to achieve resolution of symptoms and eosinophilia. Mebendazole 100 mg twice daily for 30 days alone<sup>115,116,167,171,172</sup> or in combination with levamisole<sup>173</sup> has also been reported to be effective. Ivermectin,<sup>113,174–176</sup> albendazole alone (up to 400 mg twice daily for 10 days), and combined albendazole/ivermectin<sup>177</sup> have not been shown to be effective in *M. perstans* filariasis.<sup>178</sup> In one case report, two 45-day courses of albendazole (400 mg twice daily) separated by a 2-week rest were shown to reduce microfilaremia and symptoms related to *M. perstans* infection.<sup>179</sup>

## **PREVENTION AND CONTROL**

There have been no studies of chemoprophylaxis for prevention of *M. perstans* infection, and control programs have not been attempted, although repeated doses of ivermectin (used as part of onchocerciasis control) have reduced the prevalence of *M. perstans* microfilaremia in several studies.<sup>180,181</sup>

# ***Mansonella Ozzardi***

## **INTRODUCTION**

Infection with the filarial nematode *M. ozzardi* is restricted to Central and South America and certain Caribbean islands. Although infected people are usually asymptomatic, a constellation of nonspecific symptoms have been ascribed to this infection.

## **AGENT**

Microfilariae of *M. ozzardi* were first described in blood films of Amerindians from British Guyana in 1897,<sup>182</sup> and the adult worm was described by Daniels in 1898.<sup>183</sup> Infective larvae are transmitted to the host by the bite of an infected midge (*Culicoides furens*<sup>184–186</sup> and other species<sup>187,188</sup>) or black fly (*Simulium amazonicum*<sup>188–190</sup>). There appears to be no difference between the parasites that are transmitted by the different vectors.<sup>191,192</sup>

Over the course of months to years, these larvae develop into slender, threadlike adult worms (females, 32 to 51 mm × 130 to 160 μm; males, 24 to 28 mm × 150 μm), which probably inhabit the thoracic and peritoneal cavities.<sup>183,193</sup> Adult worms have also been found in the lymphatics.<sup>194</sup> In bisexual infections, microfilariae (sheathless, 3 to 5 × 170 to 240 μm) are produced and are found in the skin and blood, generally without periodicity.<sup>195–199</sup>

## **EPIDEMIOLOGY**

The number of people infected with *M. ozzardi* is unknown.<sup>23</sup> The distribution of *M. ozzardi* is restricted to Central America, South America (Colombia, Venezuela, Guyana, Suriname, Brazil, Argentina, and Bolivia), and certain Caribbean islands (Puerto Rico, Antigua, Guadeloupe, Nevis, Dominican Republic, Haiti, Martinique, St. Kitts, St. Lucia, St. Vincent, and Trinidad). In highly endemic areas, 65% to 70% of people may have circulating microfilariae.<sup>200</sup> Although nonhuman primates, other mammals, and certain birds and amphibians can be infected with *M. ozzardi*, humans are the only significant reservoir of infection. Detailed analyses of the seasonality and ecology of *M. ozzardi* infection have not been performed. Like many other pathogenic filariae, *M. ozzardi* contains an endosymbiont of the *Wolbachia* genus.<sup>201</sup>

## **DISEASE**

Although *M. ozzardi* is generally thought to cause little or no disease in humans, several reports have clearly associated this infection with urticaria, lymphadenopathy, articular pains, pruritic skin eruptions, edema, headache, and pulmonary symptoms.<sup>168,200,202–209</sup> A form of keratitis has been associated with *M. ozzardi* infection in the Brazilian Amazon.<sup>210</sup> Eosinophilia is common.<sup>168,200,202,207,211–213</sup>

## **PATHOGENESIS AND IMMUNITY**

The pathogenesis of *M. ozzardi* infection is poorly characterized. Evidence from a small number of reported expatriates

suggests that immediate hypersensitivity may be responsible for some of the pathologic changes, eosinophilia, and IgE elevations seen in this infection.

## DIAGNOSIS

Definitive diagnosis of *M. ozzardi* infection can be made by identification of the parasite in blood or skin biopsies or by PCR in skin biopsy material.<sup>214</sup>

## TREATMENT AND PROGNOSIS

Treatment of *M. ozzardi* infection has been problematic since DEC<sup>203,215–219</sup> and benzimidazoles are ineffective against this parasite. In a single case report, ivermectin was effective in reducing symptoms and circulating microfilariae.<sup>212</sup> In a second study, four annual single doses of ivermectin (6 mg) reduced *M. ozzardi* microfilarial levels by 82%.<sup>220</sup>

## PREVENTION AND CONTROL

There have been no studies of chemoprophylaxis for prevention of *M. ozzardi* infections, and control programs have not been attempted.

# Onchocerciasis

DAVID O. FREEDMAN

## INTRODUCTION

Onchocerciasis is transmitted only within a limited geographic area of tropical Africa, Latin America, and the Arabian peninsula. For the clinician, two distinct disease entities occur. Classic clinical descriptions of keratitis, chorioretinitis, a highly inflammatory dermatitis, and the presence of subcutaneous nodules are based on observations made in patients with a lifetime of exposure to, and thus a lifetime of immunologic experience with, the etiologic agent of onchocerciasis, *Onchocerca volvulus*. With the relatively recent increase in travel to these areas of the developing world by the immunologically naive, descriptions of a different syndrome in short-term visitors with onchocerciasis has emerged.<sup>1-3</sup> Not only is there an immunologic heterogeneity between persons resident in endemic and nonendemic areas, but short-term residents are typically lightly infected. In addition, they are more likely to seek medical care earlier in the clinical course of an illness.

## AGENT

*O. volvulus* is one of eight filarial nematodes that can infect humans and is the only one that is in the genus *Onchocerca*. Of importance to those involved in control programs, a number of veterinary *Onchocerca* species that do not infect humans but are transmitted by the same blackfly vector coexist in some endemic areas. When dissected from captured blackflies, larvae of *O. ochengi*, *O. gibsoni*, *O. lienalis*, and *O. cervicalis* are morphologically indistinguishable from those of *O. volvulus*. Polymerase chain reaction (PCR) amplification of DNA from captured vectors has been used in field settings in West Africa to characterize the infecting species of onchocerca. *O. volvulus* uniformly harbors *Wolbachia* endosymbiotic intracellular bacteria, which are essential for fertility and reproduction.<sup>4-6</sup> *Wolbachia* released from dying bacteria plays a role in treatment-induced reactions<sup>7</sup> and has an as yet to be completely defined role in ongoing pathogenesis.

## History

In 1875, O'Neill first associated microfilariae present in skin with crawl-craw, an irritating papular dermatitis found in Ghana.<sup>8</sup> Leuckart in 1893 first described the adult worms in subcutaneous nodules from persons in West Africa, and Manson confirmed the microfilariae associated with these nodules to be distinct from those of *Wuchereria bancrofti*. The association between the nodules containing the adult worms

and the microfilariae causing skin disease was not made until around 1910. In 1917, Rodolfo Robles, a Guatemalan physician trained by Brumpt in France, published what is the landmark study in the history of onchocerciasis: "A New Disease from Guatemala."<sup>9</sup> He demonstrated a clear association between the nodules, the skin lesions, anterior ocular lesions, and the presence of microfilariae. He also suggested the identity of the *Simulium* vector, a finding later confirmed in West Africa by Blacklock.<sup>8,10,11</sup>

## Life Cycle

Humans are the only definitive host for *O. volvulus*. *O. volvulus*, like all nematodes, has a five-stage life cycle that involves four molts. A blackfly of the genus *Simulium* is an obligatory intermediate host in the reproduction of *O. volvulus* adult worms. Three stages occur in the intermediate host and two stages develop in the human host. Any increase in adult worm burden necessarily implies further infection by reexposure to infective L3-stage larvae from a vector, because *O. volvulus* adult worms cannot reproduce in the human host.

Infection begins with the bite of an infected *Simulium* vector.<sup>12</sup> Infective larvae (L3 stage) are deposited into the skin of a new host, where at least 6 to 12 months is required for two molts and the development of a mature adult female (L5 stage) capable of producing L1-stage larvae called microfilariae. The white, hairlike adult worms live coiled in subcutaneous or deeper intramuscular tissues surrounded by a vascularized fibrous capsule. Adult males, which are 3 cm to 5 cm long, appear to migrate from nodule to nodule to inseminate the much larger females, which range from 30 cm to 80 cm in length. The microscopic microfilariae (220–360  $\mu$ m long) are released from the nodule to migrate through subcutaneous, conjunctival, and intraocular tissues. Adult females can live for up to 14 years, each continuously producing more than 700 microfilariae per day. Estimates of the total number of adult worms in the body based on the total load of microfilariae estimated from skin snip examination indicate that considerable numbers of adult females must lie in deep impalpable nodules.<sup>13</sup> This is borne out by recent ultrasound studies. The subcutaneous microfilariae, which live for 6 to 24 months, are then ingested by a blackfly and after two molts in the vector, maturation of the infective larvae (L3 stage) takes 1 to 3 weeks.

## Genetic Variability Strains of *Onchocerca volvulus*

Extensive biologic, biochemical, entomologic, epidemiologic, immunologic,<sup>14-17</sup> and most recently DNA-based evidence<sup>18-23</sup> is available for the presence of two distinct strains or biotypes of *O. volvulus* in West Africa. The severe strain is associated with the development of ocular disease and blindness, whereas the mild strain is generally not associated with ocular disease. Severe-strain parasites predominate in savanna regions and mild strain parasites in rain-forested regions. However, strains overlap in a substantial transition zone of degraded forest where savanna strain parasites have invaded. Interestingly, it appears that apart from a 150 base-pair (designated O-150) sequence that differentiates the two strains, the level of genetic variability within the *O. volvulus* genome is extremely limited, possibly as a result of a recent genetic bottleneck.<sup>24</sup>

# Onchocerca volvulus

## Vectors

Six sibling species of the *Simulium damnosum* sensu lato complex (*S. damnosum* sensu stricto, *S. sirbanum*, *S. sanctipauli*, *S. leonense*, *S. yahense*, and *S. squamosum*), identified based on adult fly morphology and on chromosome banding patterns, are the vectors of *O. volvulus* in West Africa. Based on habitats and more recently on mitochondrial gene sequences,<sup>25-27</sup> further grouping into a savanna clade (*S. damnosum* sensu stricto, *S. sirbanum*), a rain forest clade (*S. yahense*, *S. squamosum*), and a transition zone clade (*S. leonense*, *S. sanctipauli*) is possible. *S. neavei* plays a less well-defined role in African onchocerciasis but is a well-implicated vector in eastern and central Africa.<sup>28</sup> In the Americas, both *S. ochraceum* and *S. metallicum* are distinct species complexes responsible for transmission in Central America and Venezuela. *S. exiguum* and *S. quadrivittatum* in

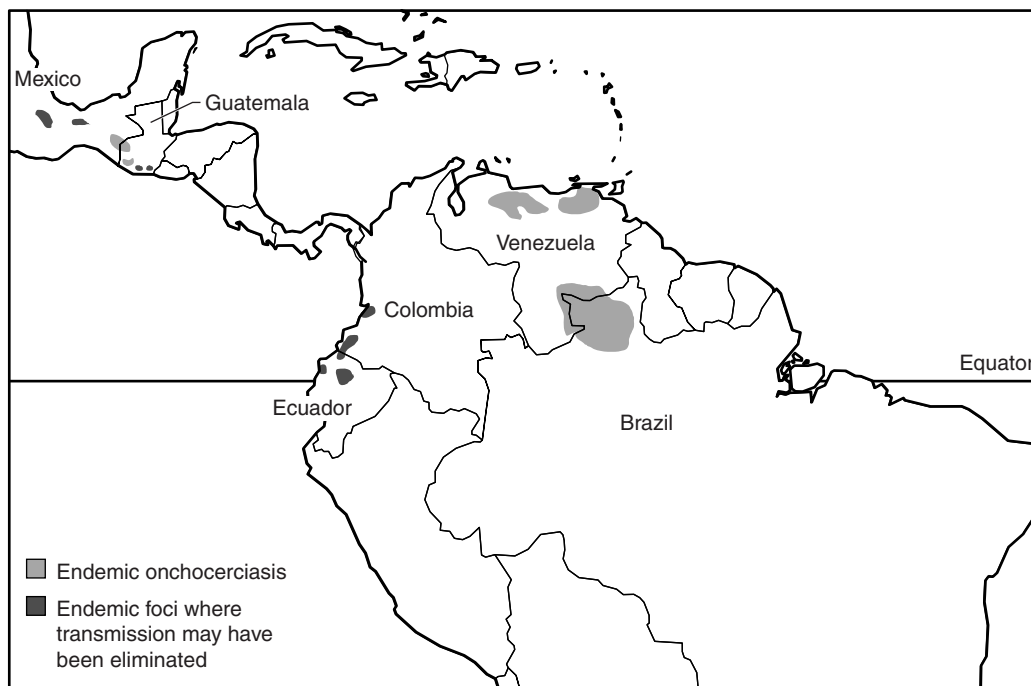

Colombia and Ecuador and *S. oyapockense* and *S. guianense* on the Brazil-Venezuela border are the important vectors in those areas.

*Simulium* lays its eggs attached to rocks and vegetation submerged in fast-flowing, highly oxygenated rivers and streams, where larval and pupal stages develop. In Africa, the vector breeds in large rivers such as the Volta, while in the Americas the vector breeds in streams and rivulets in forested areas and is less accessible to larviciding by aircraft.

## EPIDEMIOLOGY

Onchocerciasis is endemic in 34 countries, 26 in Africa, 6 in Latin America, and 2 in the Arabian peninsula. The quality of prevalence data varies from country to country, but best

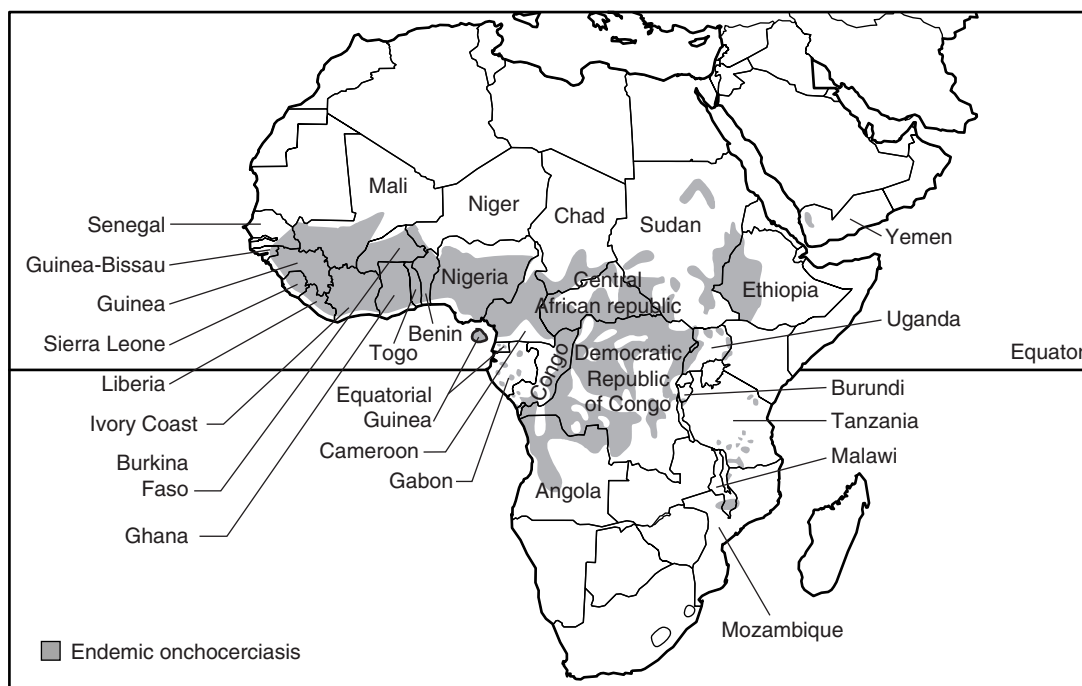

DISTRIBUTION OF ONCHOCERCIASIS IN LATIN AMERICA

current estimates are that approximately 50 million people are at risk, with 18 million people infected. There are 270,000 individuals who are blind from onchocerciasis and another 500,000 have severe visual disability.<sup>4</sup> Global disease burden in 2002 was 0.95 million disability-adjusted life-years.

Over 99% of the cases occur in sub-Saharan Africa, with almost half occurring in Nigeria and Congo. In hyperendemic villages of Africa, infection rates approaching 100% and blindness rates of 10% are not uncommon. In Latin America, distribution is focal and transmission by the vector is at least

DISTRIBUTION OF ONCHOCERCIASIS IN AFRICA AND THE MIDDLE EAST

10-fold less intense. Thus, infected individuals in Latin America have relatively low worm burdens with the result that few people are blind from the disease. Forest-strain *O. volvulus*, found in rain-forested coastal regions of sub-Saharan Africa, uncommonly causes blindness even in relatively heavily infected persons.<sup>29,30</sup>

In distinct contrast, in endemic savanna regions of Africa, a direct linear relationship between a derived parameter, the community microfilarial load, and the incidence of blindness in that community exists.<sup>29,31,32</sup> Thus, even moderate parasite burdens in those infected with the savanna strain of *O. volvulus* may result in blindness.<sup>33</sup> On an individual basis, the incidence of blindness is significantly and positively associated with increasing microfilarial burden.<sup>34</sup> DNA probe data from excised nodules demonstrate that in villages at the savanna-forest interface, mixed strain infection can occur.

Other factors influencing the epidemiology of onchocerciasis are less well defined. No known sex differences in acquisition of infection have been described. Age is related only to cumulative exposure to infection. Vector abundance varies seasonally with precipitation patterns and with dispersal patterns. No defined genetic markers have been clearly associated with risk of either disease acquisition or disease progression in onchocerciasis.<sup>35–37</sup> However, children of *O. volvulus*-infected mothers have a significantly higher risk of parasite infection and they become infected at a younger age and with increased microfilaria intensity.<sup>38</sup>

The skin lesions and intense pruritus caused by onchodermatitis make it a leading cause of morbidity in infected areas. The resulting disfigurement results in profound psychosocial consequences and isolation by the community.

Fifty percent of all infected persons live outside of the savanna and forest/transition zone regions where blinding severe-strain parasites exist. In these regions, skin manifestations are the main complications of disease. Using standardized dermatological methodology developed over the past decade, it has become apparent that the unremitting pruritus and disfiguring skin lesions were much more important than previously appreciated. The profound psychosocial implications make onchocercal skin disease a major public health problem and more than 50% of the disability-associated life-years lost due to onchocerciasis are due, not to blindness, but to skin disease.<sup>28,39–41</sup> On a community basis, there is a strong correlation between prevalence of itching and *O. volvulus* endemicity in the community. In hyperendemic communities, 30% to 40% of the population has symptomatic skin disease.

A link between onchocerciasis and epilepsy (thought secondary to erosion of nodules through the skull) has often been reported<sup>42–48</sup> but just misses statistical significance on meta-analysis.<sup>49,50</sup> A proposed link to hyposexual dwarfism is similarly elusive.<sup>42,47,49–51</sup>

The socioeconomic consequences of onchocerciasis are profound, though the disease is not itself a direct cause of mortality.<sup>52</sup> *O. volvulus*-induced blindness is, however, associated with a life expectancy that is at least 10 years shorter than that of nonblinded persons in the same area.<sup>53,54</sup> The consequences of onchocerciasis extend beyond the individual and affect family, community, and country. The common image of young boys holding sticks to guide blind, unproductive men in their twenties and thirties attests to why entire villages become economically nonviable when blindness rates reach

about 10%. Relocation of villages to healthier locales away from vector breeding sites by the rivers is an option, but the soil away from rivers may be less fertile.

## DISEASE

In symptomatic persons, an inflammatory response to the microfilarial stage of the parasite causes the dermatitis, keratitis, and chorioretinitis that are the cardinal manifestations of infection. The subcutaneous nodules, which contain adult worms encased in a fibrous capsule, evoke no inflammatory response and hence few, if any, clinical symptoms.

Of particular importance to clinicians in nononchocerciasis-endemic areas is that a nonspecific dermatitis is almost always the sole clinical manifestation of disease in short-term visitors to endemic areas.<sup>2,3</sup> Transmission of onchocerciasis is highly inefficient when compared with other vector-borne diseases such as malaria. Infection is uncommon after a short stay of a year or less in an endemic area. In a study of infected expatriates, the median duration of exposure was 2 years (range, 20 months to 6 years). In these lightly infected persons, a median period of 18 months (range, 3 months to 3 years) from the end of exposure before the onset of symptoms then passed.

## Dermatitis

The pruritus of onchocerciasis, which is secondary to tissue reaction to motile larvae as they migrate subcutaneously, is the most severe, intractable, and unresponsive to antipruritus medication that is known. In the more heavily infected persons in endemic areas, scratching and excoriation to the point of bleeding, and even suicide, occurs. An almost complete inability to sleep is common. Episodes of localized rash, erythema, and angioedema may be superimposed on the ongoing dermatologic manifestations at essentially any stage of the disease.<sup>55</sup>

A commonly recognized scheme categorizes skin disease into five groups. Within each group a category-specific grading for severity, activity, and distribution is included.<sup>28,39,41</sup> The categories are not mutually exclusive in a given patient and the clinical findings are not necessarily specific for onchodermatitis.

1. Acute papular onchodermatitis (APOD): Small pruritic papules may be scattered on limbs, shoulders, and trunk. Lesions may progress to become vesicular or pustular. Lesions may be spontaneous or occur as a reaction to ivermectin or diethylcarbamazine. Histologically, the papules are intraepidermal microabscesses; microfilariae are inconsistently present. A variable perivascular infiltrate of lymphoid origin is seen in this and most types of onchocercal skin disease. Microfilariae, when found, are in the superficial dermis and are frequently associated with lymphatics.
2. Chronic papular onchodermatitis (CPOD): Papules, which are often flat-topped, are larger but more variable in size and height than in the acute papular eruption. Dermatitis is usually symmetrical over buttocks, waist, and shoulder areas and less pruritic than in the acute eruption. Clinical hyperpigmentation and hyperkeratosis correlate histologically with epidermal acanthosis and

incontinence of pigment. This is the most common skin manifestation in hyperendemic areas.

3. Lichenified dermatitis: An intensely pruritic eruption limited to one limb, usually the leg, sowda consists of hyperpigmented papules and plaques with accompanying edema of the entire limb. Regional lymph nodes are enlarged and show prominent follicular hyperplasia suggesting that sowda is due to an aberrant humoral hyperresponsiveness in affected persons. Bacterial superinfection is common due to excoriation of the intensely pruritic lesion. Histologically, few microfilariae are found and hyperkeratosis, acanthosis, and dermal fibrosis are found. Sowda is most common in Yemen and the Sudan but is seen elsewhere in Africa.
4. Atrophy: Premature atrophy is due to degeneration of one or more of the structural elements of the skin with chronic infection. Atrophy is most common over the buttocks but can occur over limbs. Pruritus is uncommon. Clinically, fine wrinkles will appear after pushing along the skin surface with one finger. Loss of elasticity can be demonstrated by slow return to position of skin pinched between two fingers. Histologically, special stains reveal loss of elastic fibers. In order to avoid confusion with senile atrophy, the diagnosis of onchocercal atrophy should only be made in those under age 50 years.
5. Depigmentation: Areas of complete depigmentation over the anterior shin with islands of normally pigmented skin, commonly called "leopard skin," are seen in advanced onchodermatitis.

In Mexico and Guatemala, chronic skin lesions peculiar to this region are described. These include *erisipela de la costa*, a macular rash and edema of the face, and *mal morado*, a lesion associated with a reddish discoloration, particularly on the trunk and upper limbs.

Moderate to severe pruritus is the major presenting complaint in expatriates and an evanescent nonspecific maculopapular rash, which may have an urticarial component, is the main physical finding. The rash is often localized to one area of the body, usually the trunk, presumably in proximity to the few adult worms present. The long incubation period of onchocercal dermatitis and the unfamiliarity of physicians in the industrialized world with its manifestations make misdiagnosis frequent.

### Subcutaneous Nodules

Asymptomatic 0.5-cm to 3.0-cm subcutaneous onchocercomas occurring most often over bony prominences are freely movable encapsulated nodules that contain coiled masses of adult worms. In Latin America, where the vector *S. ochraceum* bites high, the nodules are often located on the head and upper body, whereas in Africa where *S. damnosum* bites lower, the nodules are most often over the hips and lower limbs. Palpable subcutaneous nodules are uncommonly found in the lightly infected expatriates.

### Lymphadenopathy

Lymphadenopathy is frequently found in inguinal and femoral areas. The so-called hanging groin results when lymphadenopathy occurs in inguinofemoral nodes in a sling of

stretched-out atrophic abdominal skin. Lymph nodes are scarred, nontender, and fibrotic.

### Eye

Involvement of all tissues of the eye has been described. Host reaction to microfilariae of *O. volvulus* as they migrate through the eye initially presents as a punctate keratitis or as snowflake corneal opacities. Individual opacities clear spontaneously to be followed by others. Free microfilariae may be visible by slit-lamp examination in the anterior chamber or aqueous humor. Long-standing infection with savanna-strain *O. volvulus* leads to sclerosing keratitis, and eventually to blindness. Sclerosing keratitis is characterized by a fibrovascular pannus and an inflammatory infiltrate at the level of Bowman's membrane. The opacity develops around the edge of the cornea and as it becomes vascularized advances toward the center. Iridocyclitis with flare and cells in the anterior chamber leads to development of synechiae, raised intraocular pressure, and secondary glaucoma. Adult *O. volvulus* does not migrate through the subconjunctiva. In contrast, the occasional subconjunctival migration of the long slender adult worm of *Loa loa*, confusingly called the eye worm, is visible to the naked eye of both the patient and the observer; lacrimation, pain, and extreme anxiety typically ensue (see Chapter 99).

Inflammatory disturbances of the retinal pigment epithelium lead to chorioretinitis, chorioretinal atrophy, and posterior ocular disease, and are thought to cause blindness in the rain forest but have also been found secondary to savanna-strain disease. The importance of optic neuritis in ocular onchocerciasis has been more appreciated recently. Optic atrophy may occur in up to 10% of the population of savanna regions. The acute phase can last for a year or more. A postneuritic optic atrophy associated with scarring and retinal pigment disturbance or with vascular sheathing of retinal vessels then ensues. Visual field loss may progress to keyhole vision or even total loss of light perception. Ophthalmologic abnormalities or intraocular microfilariae (even on slit-lamp examination) are not found in the expatriate group.

### Human Immunodeficiency Virus and Onchocerciasis

Onchocerciasis patients who are human immunodeficiency virus (HIV)-positive may have more severe skin disease when compared to those who are HIV-negative.<sup>56</sup> Impaired immunoglobulin G (IgG) and IgM responses to *O. volvulus* antigens occurs in HIV-positive persons with onchocerciasis. However, no epidemiologic association between HIV infection and onchocerciasis has been demonstrated.<sup>57</sup> Both initial microfilaria densities and efficacy of ivermectin treatment are the same in HIV-positive and HIV-negative persons with onchocerciasis.<sup>58</sup>

## PATHOGENESIS AND IMMUNITY

### Systemic Immune Responses

The parasite seems to be able to modulate potentially deleterious parasite-specific immune responses in order to live in relative immunologic harmony with its host. Severe pathologic complications are seen only in a subset of infected patients.

In *O. volvulus*-infected individuals, a highly polarized immune response to specific parasite antigens occurs. There are (1) impaired production of type 1 cytokine (interferon [IFN]- $\gamma$ ) but brisk production of type 2 cytokines (interleukin [IL]-4 and IL-5)<sup>59-62</sup>; (2) production of IL-10 both spontaneously and in response to parasite antigen<sup>1,63,64</sup>; and (3) high serum levels of both polyclonal and specific IgE and IgG4.<sup>1,62,65,66</sup> A central role for the immunomodulatory action of IL-10 has been demonstrated by examining new migrants to infected areas and by the response to ivermectin treatment. Early infection is associated with vigorous cellular responses but as infections become chronic, down-regulation is effected through IL-10.<sup>64</sup> Continued treatment with ivermectin of nonendemic patients no longer exposed to new infection showed decreased IL-10 production at follow-up without any fundamental type 2 to type 1 shift.<sup>1</sup> This effect is only transient in endemic individuals with continued exposure and re-infection.<sup>67,68</sup> A number of in vitro and circumstantial clinical studies have demonstrated a generalized depression of cellular immune responses to nonparasite antigen in *O. volvulus*-infected persons.<sup>61,69-73</sup> A prospective in vivo study showed that concurrent infection with *O. volvulus* did not prevent development of a protective antitetanus response after administration of tetanus vaccine, but heavier *O. volvulus* infection was able to attenuate the magnitude of this protective response.<sup>74</sup> The biologic relevance of the degree of generalized immunosuppression found in onchocerciasis patients remains to be proven. Several findings have implicated seemingly unrelated autoimmune pathways in the pathogenesis of disease, with a number of putative autoantigens described, but true etiologic associations have not been shown.<sup>75-82</sup>

### Immune Responses in Local Tissue

Sclerosing keratitis, the major cause of blindness resulting from infection with *O. volvulus*, is manifested by corneal opacification and neovascularization.<sup>83</sup> A biphasic recruitment of first neutrophils (see later *Wolbachia* discussion) and later eosinophils to the central cornea in response to degenerating microfilariae appears causative.<sup>84,85</sup> Direct evidence for this exists in rabbit, guinea pig, and mouse models of onchocercal keratitis. In these models, the predominately lymphocytic inflammatory ocular reaction is parasite antigen-specific, CD4+ dependent, and manifest only in animals presensitized with parasite antigen. Murine onchocercal keratitis has been demonstrated to be Th2 (IL-4)-dependent. Supporting data included corneal localization of IL-4 (but not IFN- $\gamma$ ) messenger RNA (mRNA) in both intact immunized mice and in nude mice reconstituted with immune splenocytes, as well as a failure to develop keratitis in IL-4 knockout mice. At the same time, the migration of eosinophils is IL-5-dependent as these cells are absent from the corneas of IL-5 gene knockout mice. ICAM-1 and PECAM-1 but not VCAM-1 are involved in recruitment of effectors cells to the avascular cornea.<sup>86,87</sup>

Corroborating studies on human tissue have not been performed to date due to the unavailability of corneal tissue from infected persons. Data on local ocular immune responses in human onchocerciasis are limited and only conjunctival and iris, but not corneal, tissue has been examined. A single study, however, indicates a predominance of

IL-4-producing (vs. IL-2-producing) T cells among lymphocyte infiltrates in conjunctival biopsies from patients with ocular onchocerciasis.<sup>88-90</sup> A study demonstrating a Th2-like systemic immune response in humans with well-characterized onchocercal keratitis corroborates the findings in the murine model of onchocercal keratitis.<sup>63</sup>

Local type 2 responses have been implicated in the cutaneous pathology but the associations are generally weak.<sup>91</sup> Numbers of microfilariae found in the skin of individual patients are not correlated with presence or absence of skin disease. Tissue damage is most pronounced after treatment with ivermectin and diethylcarbamazine, which kills the dermal microfilariae. In these cases, pathogenesis is secondary to eosinophil recruitment and degranulation after activation of the eotaxin and RANTES pathways.<sup>92-97</sup>

### Role of the Endosymbiont *Wolbachia*

*O. volvulus* uniformly harbors endosymbiotic intracellular bacteria, which are essential for fertility and reproduction.<sup>4-6</sup> Eradication of these bacteria, such as with doxycycline therapy,<sup>98</sup> not only sterilizes the adult females but may shorten their life span. In the absence of any known adulticidal drug, this finding has implications for treatment and control of *O. volvulus*. *Wolbachia* released from dying parasites after diethylcarbamazine or ivermectin treatment of infected individuals induces release of TNF and related mediators.<sup>7</sup> These sometimes severe post-treatment reactions (the Mazzotti reaction<sup>99</sup>) were until recently attributed to release of parasite antigen systemically. *Wolbachia* do not produce endotoxin, but their major surface proteins have been shown to induce the innate immune system through TLR-2 and TLR-4. In the murine model of onchocercal keratitis, *Wolbachia* have been shown capable of inducing the early neutrophilic response and causing corneal opacities.<sup>100</sup> A defined role for *Wolbachia* in ongoing pathogenesis in humans awaits further study.

## DIAGNOSIS

### Clinical Examination

*O. volvulus* has a quite well-defined distribution, but because of the geographic overlap with other filarial parasites, a well-taken travel or residence history by an epidemiologically cognizant physician will eliminate the need for unnecessary diagnostic investigations in those with no possible exposure. *O. volvulus*, *Loa loa*, *Mansonella perstans*, *Mansonella ozzardi*, and *Mansonella streptocerca* all may cause overlapping clinical syndromes. In suspected onchocerciasis, the history should focus on duration and intensity of exposure and its chronology with respect to an incubation period that may be 2 years or more.

A physical examination with the patient completely disrobed is necessary to detect (1) the localized dermatitis, often occurring in the buttock region, associated with either *O. volvulus* or *M. streptocerca*; (2) subcutaneous nodules; or (3) Calabar swellings of loiasis. A thorough palpation of all lymph node groups, including those in the inguinal region, will aid in the diagnosis of *Wuchereria bancrofti*, *O. volvulus*, or *M. streptocerca*. Slit-lamp examination of the eye is required to work up possible

onchocerciasis, although the yield is so low in lightly infected expatriates that it is likely unnecessary. The patient should first sit for 10 minutes with the head forward and bowed to allow microfilariae located posteriorly and inferiorly to become visible. Fluorescein angiography is the most sensitive detector of early chorioretinal lesions.

### Laboratory Diagnosis

Outside of research settings, definitive diagnosis is most often dependent on the relatively unsophisticated parasitologic demonstration of the 220- to 360-mm-long microfilariae in skin snips. In well-equipped clinical settings, biopsy or ultrasound demonstration of adult parasites in any nodules that are present can be diagnostic.

### Skin Snips

Skin microfilariae are optimally detected utilizing skin snips taken down to the level of the dermal papillae. This type of skin biopsy employs either a razor blade to slice a thin piece of skin which has been tented up with a needle or a corneoscleral biopsy instrument to obtain 1 to 2 mg of skin bloodlessly.<sup>101,102</sup> The ability to use disposable materials with the former technique in areas where the risk of blood-borne pathogens is high and sophisticated sterilization is not available is a real advantage. A microscopic count of the highly motile microfilariae migrating out of six biopsies, one from over each scapula, iliac crest, and lateral aspect of each calf, is performed after incubation of the skin snips with saline in microplate wells at 37°C. In heavier infection, motile microfilariae will be visible emerging from the skin snip under low-power microscopy in 10 to 60 minutes, but negative snips should be covered to prevent evaporation and checked periodically for at least 24 hours. A heavily infected person may have more than 100 microfilariae per milligram of skin. In Africa, the highest yield will be from the iliac crest and in Latin America from over the scapula. In expatriates, the majority of infected persons do not have microfilariae in their skin and those that do have very low counts.

Deep punch biopsy of the skin is not necessary and multiple skin snips will have a higher yield than one random traumatic deep biopsy. Blood contaminating a skin snip may result in one of the blood-borne microfilaria escaping into the specimen, with *M. ozzardi* (which lives in superficial capillaries) most frequently incriminated. If the patient has been in an area endemic for *M. streptocerca*, it is then necessary to fix the skin and to stain the microfilariae for identification. In contrast to *M. streptocerca*, *O. volvulus* microfilariae have anterior nuclei that are side by side, a caudal space free of nuclei, and a tail tapered to a fine point. *M. streptocerca* is most often found in snips taken over the upper trunk.

### Blood Examination

Because of the geographic overlap in the distribution of filarial parasites that may cause overlapping clinical syndromes, examination for circulating microfilaremia is often necessary. A properly timed and processed blood sample is thus vital (see Chapters 98 and 99).

### Urine and Other Fluids

Microfilariae of *O. volvulus* have been found in the urine of some infected persons during mass epidemiologic studies in hyperendemic regions, with microfilarial counts being well correlated with skin counts.<sup>103</sup> Examination of the urine, however, has no utility as a general diagnostic technique and is no substitute for properly performed skin snips in the diagnostic workup of a single patient. Cerebrospinal fluid microfilariae can be seen in severe *O. volvulus* infection.

### Demonstration of the Adult Parasite

A coil of hairlike white worms discovered in an excised subcutaneous or intramuscular nodule in the appropriate epidemiologic setting is diagnostic of onchocerciasis on visual inspection. Most nodules have only 3 to 5 adults in them, though nodules containing as many as 50 have been found.

### Serology

Serologic testing for *O. volvulus* IgG is not generally available and when done usually utilizes a crude antigenic preparation of a nononchocercal filarial parasite. Standardization is often poor; a positive result, at best, cannot differentiate between the eight filarial species and, at worst, may cross-react with other helminthic infections like strongyloidiasis. Despite the lack of specificity, the sensitivity of this type of serology is almost 100%. Most people resident in endemic areas will have antibodies whether or not they are currently infected. Thus, serologic evaluation in filarial disease is helpful only in two situations: (1) in persons exposed to or infected with filarial parasites who are originally from nonendemic areas and were presumably seronegative initially; and (2) to detect a quantitative decrease in antibody levels that may occur as a response to definitive therapy.

### Eosinophil Count

The total eosinophil count is unhelpful diagnostically as it is often but inconstantly elevated in onchocerciasis. Recently infected temporary residents may have moderately elevated eosinophil counts but counts are normal in up to 30%. Persons with chronic long-standing infection may also have normal eosinophil counts or may have eosinophilia due to parasitism with another helminth.

### IgE Levels

Serum IgE levels may be elevated in onchocerciasis, but high levels are an inconstant finding and nonspecific.

### Ultrasound Examination

Adult worms in suspect onchocercomata will produce a central, relatively homogeneous echogenic area containing echo-dense particles with a lateral acoustic shadow. The utility of random ultrasound examination for occult nodules has not been established.<sup>104–107</sup> Sequential ultrasonographic monitoring of nodules after macrofilaricidal therapy can provide information on drug effect.

## Mazzotti Test

A 50-mg dose of diethylcarbamazine (DEC, Mazzotti test) can be given to a patient suspected of harboring *O. volvulus* but in whom no microfilariae can be detected after a rigorous and unfruitful search of blood, skin snips, and after a careful ophthalmologic examination. Within 15 minutes to 24 hours, but most often within 3 hours, the infected patient will develop pruritus with or without erythema over involved areas as microfilariae die in the skin.<sup>99,108,109</sup> Severe reactions in both skin and eye may occur in more heavily infected patients, emphasizing the importance of reserving this maneuver for very lightly infected persons. A patch test performed by applying topical DEC to a small area of skin in order to provoke a localized Mazzotti reaction<sup>110,111</sup> is a highly sensitive and specific diagnostic test in children under the age of 15 years, but the requisite drug and standardization materials are not readily available in the United States.

## DNA Diagnosis of Individual Patients

Detection of parasite DNA in routine skin snips by PCR amplification of O-150, an *O. volvulus*-specific 150-bp repeated genomic DNA family, is recognized as the most sensitive available technique for detecting low-level infections in individual patients.<sup>112–115</sup> This technique, available only in the research setting, is of special importance in the diagnosis of expatriates who are typically lightly infected. A standard uncomplicated PCR protocol is applied to DNA extracted from skin snips that are fresh, frozen, or preserved in ethanol. Unanswered questions include how long parasite DNA remains in the skin after treatment or the natural death of adult worms and how extensively parasite DNA is distributed in the body in light infections.

## Diagnostic Difficulties

Scabies, insect bites, hypersensitivity reactions, miliaria rubra, and contact dermatitis enter the differential diagnosis of acute pruritic disease. In expatriates, Calabar swellings (see Chapter 99), clinically similar episodes of localized rash, and mild angioedema can mimic onchodermatitis. Tuberculoid leprosy and eczema should be considered if there are chronic skin changes. Dermatomycoses, previous trauma, and yaws can also cause hypopigmented skin lesions. Onchocercal chorioretinitis must be differentiated from choroiditis due to syphilis, tuberculosis, or toxoplasmosis. Optic neuropathy in endemic areas may be due to nutritional optic atrophy, syphilis, or primary glaucoma. In expatriates with a highly suggestive clinical and epidemiologic history (i.e., being a travel partner of a skin snip-positive patient) but with negative skin snips and no nodules, presumptive diagnosis can be made on the basis of the Mazzotti test and serology if available.

## TREATMENT AND PROGNOSIS

No available nontoxic agent is able to kill the long-lived (14 years) adult worms of *O. volvulus*. Because the pathologic sequelae of *O. volvulus* infection are entirely due to the microfilariae in skin and ocular tissue, repeated microfilaricidal therapy is necessary for morbidity reduction.

## Ivermectin

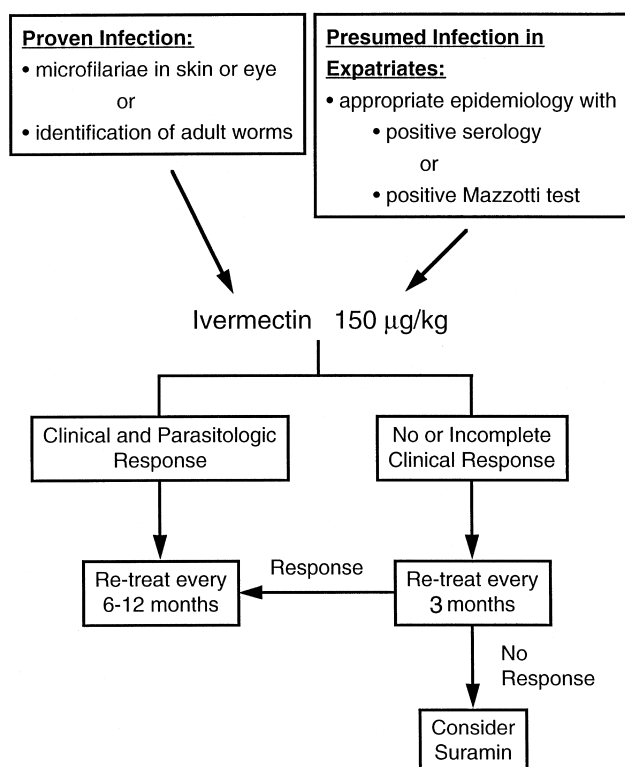

Ivermectin, a semisynthetic macrocyclic lactone originally synthesized in the 1970s for veterinary use, is the most potent anthelmintic agent ever developed.<sup>116</sup> Receptor-mediated hyperpolarization of cells after an influx of negatively charged ions occurs utilizing a novel glutamate-sensitive chloride channel present in nematodes.<sup>117</sup> The drug is well absorbed orally, excretion is almost entirely in the feces, and the serum half-life is 12 hours.

Large field trials in Africa in the 1980s established ivermectin as the treatment of choice in a single oral microfilaricidal dose of 150 µg/kg administered every 6 to 12 months.<sup>118,119</sup> Skin microfilariae are killed within days though maximum reduction may not occur for up to 2 weeks. Ocular microfilariae counts do not begin to be reduced for at least 2 weeks. Further microfilarial production is suppressed for 6 months before once again reaching levels that lead to renewed transmission at about 12 months. Annual treatment, as has been practiced over the years in control programs, effectively reduces progression and rates of ocular disease including blinding and skin disease as manifest by pruritus.<sup>31,120–123</sup> Advanced eye disease and existing blindness is not reversed. Higher doses of ivermectin given yearly do not have enhanced effect on viability or fecundity of female adult worms and cause significant side effects.<sup>124,125</sup> Increasing the frequency of ivermectin administration to every 3 months decreases microfilaria production up to threefold and may permanently impair fecundity.<sup>124–126</sup> Effect of such regimens on total adult life span is unclear.

Pruritus in lightly infected expatriates may be refractory to annual or 6-month therapy and many clinicians find it necessary to treat more aggressively with standard doses for the first 2 years or so (Fig. 100-1).<sup>127–129</sup> Ivermectin administration should be titrated to symptoms and may be given as often as every 3 months. Appropriate duration of therapy in those without further exposure to transmission is not known. While annual treatment in these cases should theoretically be offered for the possible 14-year life span of the adult worm, clinical experience is that most patients stop returning after several years, so likely are failing to develop recurrent symptoms after several years of therapy.

Ivermectin by itself has no intrinsic pharmacologic effects in humans and is remarkably nontoxic in usual treatment doses. Fever, pruritus, urticaria, myalgia, painless swelling of the limbs and face, and tender lymphadenopathy are not severe and occur mostly within 1 day of treatment.<sup>130,131</sup> Symptomatic treatment with analgesics and antihistamines is generally sufficient. Severity is in general in proportion to the microfilarial load. Postural hypotension occurs in approximately 1 in 1000 patients but can be eliminated if patients are routinely instructed to rest in bed if dizziness occurs. Reactions are diminished on subsequent treatments of individuals or populations. Ivermectin appears to be safe in pregnancy but treatment is best postponed until after delivery.<sup>132</sup>

In co-infected patients with high levels of microfilaremia due to *Loa loa* infection, caution must be exercised in the use of ivermectin to avoid causing encephalopathy (see Chapter 99) due to *L. loa* microfilaria that enter the central nervous system after treatment.<sup>133–138</sup> In resource-rich settings, plasmapheresis may be used to reduce *L. loa* microfilaremia in co-infected

**FIGURE 100-1** Treatment algorithm for individual patients.

patients prior to administration of ivermectin. Mass treatment with ivermectin for onchocerciasis is difficult in loiasis endemic areas in the absence of the ability to ascertain which individuals might be heavily infected with *L. loa*. Such co-infected areas have been avoided in the past, but rapid epidemiologic assessment tools have been developed to allow for close monitoring and rapid treatment of ivermectin-induced *L. loa* reactions after identification of a community as high risk for such occurrence.<sup>139</sup> Such protocols have not been field tested at this time. Ivermectin resistance has been reported in a few patients in Ghana but does not appear to be clinically important in any area of the world at present.<sup>140</sup>

### Doxycycline

Doxycycline 100 mg/day for 6 weeks leads to death of the endosymbiotic *Wolbachia* found in *O. volvulus* worms, followed by complete cessation of early embryogenesis for at least 18 months, and thus production of transmissible microfilaria for a longer period.<sup>98,141,142</sup> This is in contrast to ivermectin which kills larvae during a later stage of intrauterine microfilaria production with the result that early embryos survive to become microfilaria that are transmissible again within a year or less. Higher doses of doxycycline may have longer duration of effect. Shorter duration of therapy appears ineffective. Six weeks of doxycycline is not a practical public health strategy for mass treatment programs. Nevertheless, since ivermectin therapy alone may not be able to interrupt transmission (see later discussion), combination therapy for varying periods is worthy of further investigation. In the treatment of individual patients, there is no evidence at this time

to suggest that the addition of doxycycline to conventional ivermectin strategies (see previous discussion) has any benefit with respect to symptom relief or total duration of therapy.

### Diethylcarbamazine

Diethylcarbamazine (DEC) is a piperazine derivative with microfilaricidal but not adulticidal activity used for over 40 years prior to the introduction of ivermectin. Due to frequent unacceptable reactions to dying microfilariae, ranging from urticaria and angioedema to hypotension and death, DEC should no longer be used for microfilaricidal treatment of this parasite. Reactions are related to microfilarial load so that the 50 mg used for the Mazzotti test in a patient with negative skin snips and a normal slit-lamp examination is thought to be safe.

### Suramin

Suramin is the only available agent adulticidal to *O. volvulus* and is extremely toxic, necessitating hospitalization for several days with each dose. The original regimen of weekly 1-g doses given for 6 weeks is clearly unsafe. Toxicity includes a fatal progressive wasting syndrome, exfoliative dermatitis, progression of chorioretinitis, and development of optic atrophy. Better-tolerated weekly escalating dose regimens, which deliver 4 g or 5 g total, have been developed but are still not completely without risk and have the disadvantage that at least 34% of adult worms are viable 1 year later.<sup>143–145</sup> Because regular ivermectin treatment almost always controls symptoms and prevents development of disease, suramin treatment is rarely if ever undertaken nowadays. One exception may be in individuals with severe hyperreactive onchodermatitis whose symptoms cannot be controlled with repeated aggressive ivermectin therapy. Suramin is also a potent microfilaricide but with delayed effect. Skin microfilaria counts remain unchanged for at least 6 weeks.

### Nodulectomy

Periodic removal of palpable nodules to reduce the microfilarial load and the ensuing pathologic changes has been pursued with success for many years in Latin America. In Africa, where nodules are deeper, more numerous, and less accessible, this strategy appears to be ineffective. Removal of a single nodule in an expatriate with no further exposure anticipated may be considered as it may represent the only nidus of infection.

### Adulticidal Drugs

Despite intensive efforts at drug discovery, no nontoxic adulticides have been identified. Amocarazine and moxidectin, two recent candidates, are no longer in development.

## PREVENTION AND CONTROL

### Prophylaxis

There are no effective vaccines or chemoprophylactic drugs. For expatriates or others with sufficient resources, personal mosquito protection using repellents is likely of benefit.

As *Simulium* spp. are daytime biters, bednet programs in place for malaria control have no effect of onchocerciasis transmission.

In contrast to malaria or some other parasitic infections, only limited evidence exists for the development of any degree of protective immunity to *O. volvulus* in populations with long-term natural exposure to the parasite. Perhaps for this reason, efforts at development of a vaccine against onchocerciasis have been disappointing. In experimental animals, which are not naturally permissive hosts for *O. volvulus*, a protective immune response can be induced after inoculation with live radiation-attenuated L3-stage larvae. Despite the cloning and expression of several dozen *O. volvulus* recombinant antigens, none has been effective enough in animal screens to be considered for human trials.

## Vector Control

The Onchocerciasis Control Program (OCP), funded by the World Health Organization (WHO), the World Bank, and the United Nations Development Program, extended from 1974–2002 over 11 countries of West Africa most affected by blinding savanna-strain *O. volvulus*.<sup>121,146,147</sup> A strategy of aggressive vector control using aerial larvaciding of 50,000 km rivers combined with annual ivermectin treatments (added in 1988) essentially interrupted transmission in the area under control. It is estimated that 35 million people were protected from infection, 10 million children have been born into areas that were free of disease transmission, and between 125,000 and 200,000 people have been prevented from going blind. Because rapid development of the larvae necessitates weekly treatment of the rivers, the program cost over \$550 million and was unsustainable. Because infected blackflies will invade from around the perimeter of the controlled region and infected individuals will continue to migrate into controlled areas, maintenance of the success of the OCP will depend on establishment of ongoing ivermectin treatment programs.

## Mass Ivermectin Distribution

Building a sustainable infrastructure for the mass community-based distribution<sup>148,149</sup> of the microfilaricide ivermectin has become the primary control strategy on a global basis. The Mectizan Donation Program (MDP) is a unique and generous initiative established in 1988 by Merck & Company, the manufacturer of ivermectin, to provide free drug to any governmental or nongovernmental program that can demonstrate need and capability to distribute it<sup>150,151</sup>; 250 million doses have been distributed to 2002.

The African Program for Onchocerciasis Control (APOC), to run from 1995 to 2009, assists 18 affected African countries outside the original OCP area in establishing sustainable national programs for ivermectin distribution with the hope that national governments will take over after 2009.<sup>31,120,121</sup> Directed by WHO, initial funding has come from the World Bank, but contributions from multiple other donors will be required to completely fund the initiative. Merck has committed over 400 million ivermectin tablets valued at over \$200 million. The strategy is based on annual mass treatment with ivermectin to communities with greater than 40% prevalence of infection in order to break the transmission cycle by eliminating microfilariae available to vectors from the skin of

infected persons. The expense and logistics of performing detailed parasitologic diagnostics in individual communities has led to the development of simplified rapid epidemiologic mapping tools for identification of high-priority areas for ivermectin distribution. There is no nonhuman reservoir of *O. volvulus*; but unfortunately current calculations that take into account expected coverage rates and the known levels of microfilaria recurring in the skin 1 year after treatment predict that transmission cannot be broken with the current strategy.<sup>152,153</sup> Thus, morbidity will be significantly reduced but without breaking transmission, so the treatment programs might have to be continued in perpetuity. Three-monthly ivermectin treatment does permanently affect microfilaria production and may even prove to shorten adult female life span but is likely not a sustainable strategy in the African context.<sup>125–127</sup> APOC distributed 25 million tablets of ivermectin in 2002.

OEPA (Onchocerciasis Elimination Programme in the Americas) is slated to run from 1991–2007 and aims to eliminate clinical onchocerciasis by 2007 as well as interrupt transmission using a strategy of biannual ivermectin treatment and 85% coverage of affected communities. Six countries are covered (Brazil, Colombia, Ecuador, Guatemala, Mexico, and Venezuela), and at least Mexico will implement 3-monthly therapy to better have a chance at interrupting transmission.

# Zoonotic Filariasis

MARK L. EBERHARD

## INTRODUCTION

Zoonotic filariasis is human infection with a filarial parasite that normally parasitizes some other animal host. As is typical of filariae, obligate development occurs in an appropriate arthropod intermediate host and transmission is through the bite of an infected vector. In this regard, transmission of filariasis, including zoonotic infections, has a greater likelihood of occurring in tropical or subtropical climates. This may be due, in part, to a wider diversity of species and greater number of biting insects throughout the year, hence a transmission season that may be year-round. However, as a general rule, a far greater number and range of types of zoonotic infections occur in temperate than in tropical regions. Any unique aspects of zoonotic filarial infections limited to the tropics is a reflection only of the geographic distribution of a particular species of parasite involved. Zoonotic filarial infections, therefore, are neither restricted nor unique to the tropics.

## AGENT

The first well-recognized report of human infection with a zoonotic filaria is attributed to Addario<sup>1</sup> in 1885, who described a case from Italy and called the parasite *Filaria conjunctivae*. It was Desportes,<sup>2</sup> working in Paris in 1939 and 1940, who correctly recognized that *F. conjunctivae* infection was actually caused by species of *Dirofilaria*, and he applied the name *Dirofilaria conjunctivae* to these zoonotic infections. Although these subcutaneous infections were seen in various anatomic locations, the term *conjunctivae* was applied because of the marked periorbital involvement in many cases. It was not until 1965, however, that Orihel and Beaver<sup>3</sup> concluded that *D. conjunctivae* infection in the United States is most often caused by *Dirofilaria tenuis*, a parasite of raccoons (*Procyon lotor*), whereas in Europe, the former USSR, Africa, Southeast Asia, and elsewhere, these infections are commonly caused by *Dirofilaria repens*, a natural parasite of dogs and other mammals in those areas. Since then, several additional species of *Dirofilaria* have been recognized as causes of subcutaneous infection in humans.<sup>4</sup> Subcutaneous infections caused by members of the genus *Dirofilaria* probably constitute the most commonly recognized zoonotic filarial infections in humans.<sup>5-7</sup>

The second most commonly encountered form of zoonotic filarial infection, that caused by the dog heartworm, *Dirofilaria immitis*, was first reported by Faust and coworkers<sup>8</sup>

in 1941 from the vena cava of a woman in New Orleans. Infections with *D. immitis* most frequently result in a well-circumscribed lesion in a lobe of the lung and are commonly referred to as coin lesions.<sup>4</sup> These infections are widely reported from around the world, and large series of cases have been described.<sup>9</sup>

More recently, several other genera of filariae have been recognized with some frequency as causes of zoonotic infections. These include *Dipetalonema*-like worms,<sup>10-16</sup> *Onchocerca*,<sup>17-26</sup> and *Brugia*.<sup>27-41</sup> These infections have involved recovery of adult worms in tissue biopsy or surgically excised specimens, although occasionally worms have been recovered free from the surrounding tissues.

On occasion, microfilariae that did not correspond to known human species have been found in skin or blood. These include *Brugia* species,<sup>34</sup> *Mansonella rhodhaini*,<sup>42</sup> *Meningonema peruzzii*,<sup>43,44</sup> *Microfilaria semiclarum*,<sup>45</sup> *Microfilaria bolivarensis*,<sup>46</sup> *Dirofilaria*-like,<sup>47</sup> and *Dipetalonema*-like species.<sup>48</sup> The presence of microfilariae in skin, blood, or cerebrospinal fluid (CSF) indicates the presence of adult male and female worms somewhere in the host tissues.

Of the six or seven genera of filariae most often recognized as causing zoonotic infections, including *Dirofilaria*, *Brugia*, *Onchocerca*, *Mansonella*, *Meningonema*, *Loaina*, and *Dipetalonema*-like, all are in the family Onchocercidae (superfamily Filarioidea, order Spirurida),<sup>49</sup> and, with one exception, belong to one of two subfamilies, *Dirofilarinae* or *Onchocercinae*. The exception, *Meningonema peruzzii*, is in the subfamily *Splendidofilaria* (family Onchocercidae). Although human infections have been reported with filariae from a wide range of mammalian hosts, as far as is known no avian, reptilian, or amphibian filariae have caused human infection.

For ease of review, zoonotic filariae are discussed according to the tissue or organ that they infect in the human host. This information is summarized in Table 101-1.

## EPIDEMIOLOGY

The actual, and potential, distribution of zoonotic filariasis is worldwide, depending on the species of filaria. The potential for any given individual to acquire a zoonotic filarial infection is quite low. It would seem that spending an appreciable amount of time outdoors exposed to insect bites is the greatest risk factor. However, there must be other factors besides exposure to infective bites that contribute to infection, since it is likely that nearly everyone who spends time outdoors occasionally will be bitten by an infected insect and exposed to infective filarial larvae. However, in the majority of people, these infective larvae apparently do not survive to undergo development.

Regardless of the type, all zoonotic filariae are transmitted to humans through the bite of infected arthropods. As far as is known, transmission of most zoonotic filarial infections has been through mosquito bites, although *Culicoides* and *Simulium* are undoubtedly responsible for transmitting zoonotic *Onchocerca* and *Mansonella* infections. Other known filarial vectors, such as mites, ticks, and tabanid flies, also could be responsible for transmitting infections to humans, although no human infections due to filariae transmitted by these vectors are recognized to have occurred.

**Table 101-1** Summary of Major Zoonotic Filarial Infections Reported to Cause Infection in Humans

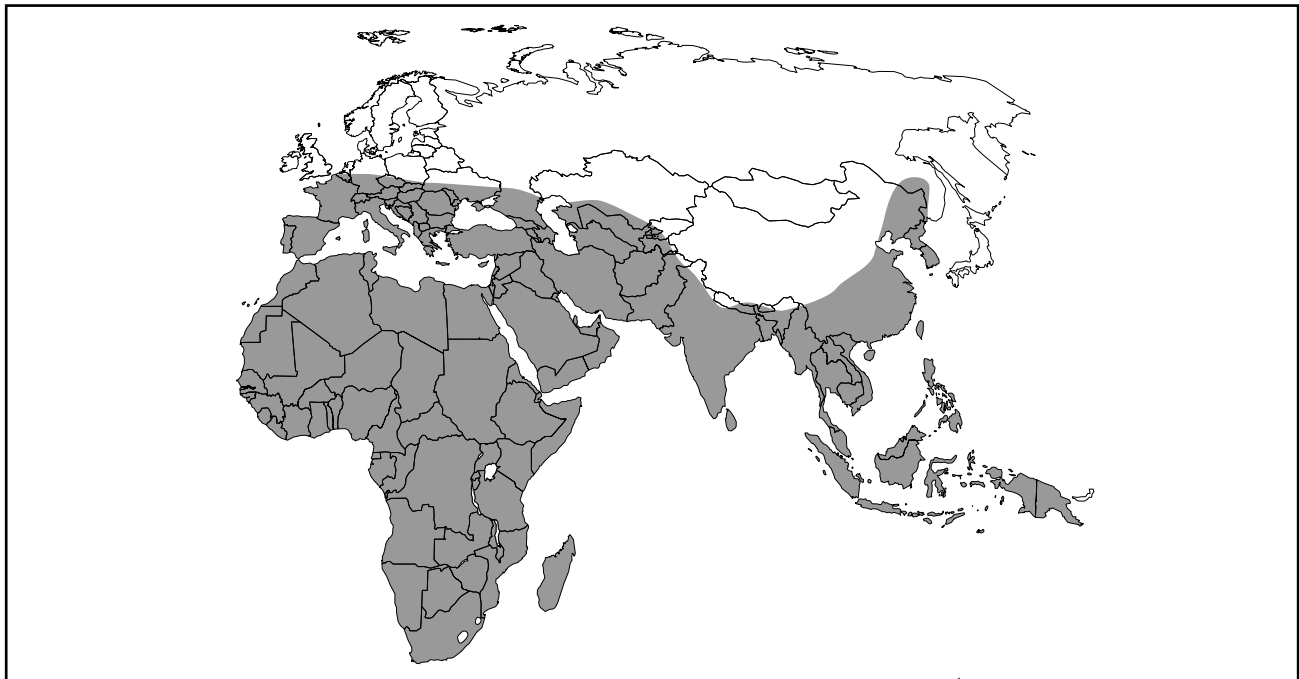

Site	Parasite	Natural Host	Geographic Distribution in Natural Host	Geographic Distribution of Reported Human Cases
Lung	<i>Dirofilaria immitis</i>	Dog	Cosmopolitan	North and South America, Australia, Japan, Europe
Skin, subcutaneous tissue	<i>Dirofilaria tenuis</i>	Raccoon	North America	North America
	<i>Dirofilaria repens</i>	Dog	Europe, Russia, Middle East, Africa, Southeast Asia	Europe, Russia, Middle East, Africa, Southeast Asia
	<i>Dirofilaria ursi</i>	Bear	North America, Japan	North America, Japan
	<i>D. immitis</i>	Dog	Cosmopolitan	North America, Japan
	<i>Dirofilaria striata</i>	Bobcat, wildcats	North and South America	United States
Eye	<i>Onchocerca</i> spp.	Ungulates	Cosmopolitan	North America, Europe, Russia, Japan
	<i>Mansonella rhodhaini</i>	Chimpanzee	Africa (Gabon)	Africa (Gabon)
	<i>D. tenuis</i>	Raccoon	North America	North America
	<i>D. repens</i>	Dog	Europe, Russia, Africa, Southeast Asia	Europe, Russia, Africa, Southeast Asia
	<i>D. immitis</i>	Dog	Cosmopolitan	Australia, Southeast Asia
	<i>Loaina</i> spp.	Rabbit, kangaroo	North America, Australia	South America, Australia
	<i>Dipetalonema</i> -like	?	?	North America
	<i>Onchocerca</i> spp.	Ungulates	Cosmopolitan	United States, Hungary
	<i>Brugia ceylonensis</i>	Dog	Sri Lanka	Sri Lanka
Lymphatics	<i>Brugia</i> spp.	Rodents, carnivores	North America, Africa, Southeast Asia	North and South America, Africa
Blood	<i>Microfilaria bolivarensis</i>	?	South America (Venezuela)	South America (Venezuela)
	<i>Dipetalonema semiclarum</i>	?	Africa (Congo)	Africa (Congo)

The geographic distribution of the filariae that are recognized as causes of zoonotic infections is, for the most part, poorly defined, and the distribution of human infections is even more patchy. More zoonotic infections are detected and identified in North America and Europe than in Latin America, Africa, or Southeast Asia. This is illustrated by the number of zoonotic *Brugia* infections reported from the United States<sup>28,30–32,34,35,38–40</sup> and the large series of zoonotic *D. repens* cases documented by Pampiglione and co-workers<sup>50–53</sup> from Italy. However, this in no way implies that the true incidence of zoonotic infections is higher in temperate than in tropical regions. This disparate distribution of known cases undoubtedly reflects better access to health care and a much different level of health-related concerns on the part of both patient and clinician.

Equally poorly defined are other factors that may contribute to filarial infections. There may well be seasonality to the transmission potential, and this would be more marked in temperate than in tropical areas. Mosquito-transmitted zoonotic infections are almost certainly acquired during the warmer summer months in the northern United States and Canada, for instance, than during the winter months. In the tropics, other factors, such as rainfall, availability of breeding sites, and so on, are probably more important in determining the likelihood of transmission than is temperature. Proximity to the natural definitive host also may play an important role in acquisition of infection. In the case of zoonotic infection with *D. immitis* or *D. repens*, both natural infections of dogs, having an infected dog in the household or in the neighborhood probably increases the risk of exposure to infected mosquito bites. Numerous wild animals, such as raccoons and rabbits,

which harbor *D. tenuis* and *Brugia leporis*, respectively, commonly live in residential areas and persons who “never travel to the country” may be exposed in their own backyard or community park.

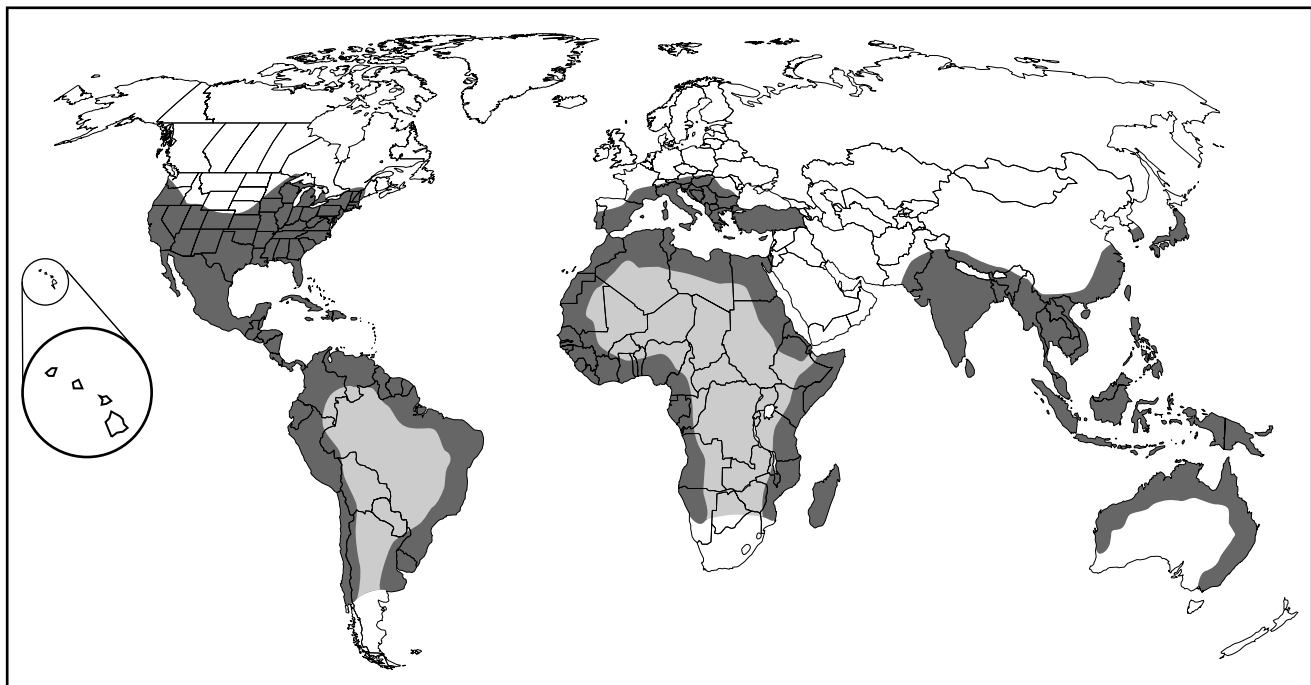

Unfortunately, there is no way to estimate the number of zoonotic filarial infections acquired each year, nor is it possible to gauge the percentage of infections that are detected and diagnosed each year. Many of these zoonotic infections, especially those caused by species of *Dirofilaria*, are now becoming more widely recognized by clinicians and pathologists, and unless there is something unusual about the case, they are not routinely reported in the literature. The more unusual infections, such as those caused by *Brugia* or *Onchocerca*, when recognized, still hold enough interest to merit publication. Overall, however, it is probably safe to say that hundreds of zoonotic infections are attributable to various *Dirofilaria* species each year. On the other hand, the author is aware of no more than about 30 reported cases of zoonotic *Brugia* infections, all but one or two occurring in the Western Hemisphere. The possibility of zoonotic *Brugia* infections, especially in Southeast Asia, would seem to be high, especially after Edeson and others were able to demonstrate experimental infections in humans with *Brugia pahangi*.<sup>27</sup> However, it would be nearly impossible to recognize and distinguish a zoonotic *B. pahangi* infection from a *Brugia malayi* infection based on the morphologic aspects of either microfilariae in blood smears or adults in lymphatic tissues. Some zoonotic filarial infections have been recognized on only several occasions. These include 10 reported cases of *Onchocerca*,<sup>17–20</sup> several cases of *Dipetalonema*-like worms,<sup>10–16</sup> three observations of a *Loaina*-like worm,<sup>54,55</sup> and one instance of *Macacanism*.<sup>56</sup>

*Dirofilaria repens* in Dogs and Other Carnivores

■ Approximate distribution

*Note:* The actual distribution may extend farther northward into the Scandinavian countries and also be more extensive in central Asia. The parasite is not recognized to occur in the Western Hemisphere, nor in Australia. Zoonotic human cases have been reported from virtually all recognized endemic areas.

*Dirofilaria immitis* in Dogs

■ Approximate geographic distribution

\* Distribution of recognized zoonotic cases

*Onchocerca* spp.

■ Geographic distribution

\* Known human cases

Although most often caused by a single, infertile worm, zoonotic filarial infections occasionally are recognized to be caused by more than one worm. This has been most evident in cases in which gravid female worms were observed or in which microfilariae were detected. Both instances require not only the presence of a male worm but also that both worms survive long enough to reach sexual maturity and mate. This situation has been reported at least four times in the case of *Dirofilaria* infections,<sup>57–60</sup> three times in *Brugia* infections,<sup>34,35,37</sup> and once in a *Dipetalonema*-like infection.<sup>48</sup> Orihel and colleagues<sup>61</sup> have described a different situation in which two *D. repens* worms, both female and both unmated, were recovered from the same person about 10 months apart. The authors concluded that the worms were from the same inoculum but appeared in the conjunctiva at different times. Female worms, at least in the case of *Dirofilaria*, are recorded about three times more often than male worms, although there is no biologic basis for this difference. Again, Orihel and colleagues raised the possibility that infection with male worms occurs as frequently but goes unrecognized more often.<sup>61</sup>

## DISEASE

The disease, its clinical manifestations, and pathologic findings are reflected in the anatomic site of infection and can, for ease of discussion, be broken into four major categories of lesions: subcutaneous, lung, eye, and lymphatic.

### Subcutaneous Infections

Several different filarial parasites cause subcutaneous or connective tissue infections, including species of *Dirofilaria*, *Onchocerca*, and *Dipetalonema*-like. The vast majority of skin and subcutaneous lesions are caused by one of several species of *Dirofilaria*. In Europe, Africa, and Southeast Asia, *D. repens* is most often incriminated as the etiologic agent and would be at the top of the list of suspected species. In the United States and Canada, *D. tenuis* is most frequently involved, although, in decreasing order, *D. ursi* of bears (or *D. subdermata* of porcupines), *D. striata* of bobcats, and *D. immitis* of dogs are also recognized to cause human infection. Subcutaneous infection due to one of these *Dirofilaria* species most commonly results in the appearance of a small (0.5 to 1.5 cm), discrete nodule that is noticed by the patient anywhere from several days to several weeks prior to surgical removal.<sup>4,62</sup> On sectioning, one or more sections of encased filarial worm are evident (Fig. 101-1). These nodules can be either painless or painful and with or without signs of local inflammation. Occasionally, there has been some sensation that a moving worm was present, and in these cases, there tends to be more generalized edema and swelling and a less discrete nodule. These later cases likely represent worms that are beginning to reach the end of their sojourn in the human body but have not yet become fully enclosed in a granulomatous nodule. There is little systemic sign of infection, although some patients may have an elevated eosinophilia; generally, the presentation is otherwise unremarkable. Zoonotic *Dirofilaria* infections can be expected to occur in almost any anatomic location, but some of the more unusual locations include the bladder,<sup>63</sup> spermatic cord<sup>64–68</sup> or epididymis,<sup>69</sup> liver,<sup>70</sup> and mouth.<sup>71</sup>

**FIGURE 101-1** A subcutaneous nodule caused by a zoonotic filarial infection due to *Dirofilaria tenuis* from a case in South Carolina. Note the proximity of the nodule to the skin surface and the numerous sections of a single parasite encased in the nodule, which measured approximately 8 mm in diameter. (H&E stain.)

### Eye Infections

A report of a worm in, on, or near the eye of a patient (Fig. 101-2) is always a dramatic occurrence for both patient and clinician. Patients frequently report the sensation of “movement of an object” in or near the eye, and the physician

**FIGURE 101-2** Clinical photograph of coiled *Dirofilaria repens* on the conjunctiva. (From Pampiglione S, Canestri Trotti G, Rivasi F: Human dirofilariasis due to *Dirofilaria* [*Nochtiella*] *repens*: A review of world literature. *Parassitologia* 37:149–193, 1995.)

**FIGURE 101-3** Clinical photograph of facial edema in a patient with periorbital soft tissue swelling due to *Dirofilaria tenuis* infection. (From Kersten RC, Locastro AJ, Eberhard ML, et al: Periorbital dirofilariasis. *Ophthalmic Plast Reconstr Surg* 10:293–296, 1994.)

can occasionally see the worm in the conjunctiva, on the eye itself, or in the anterior and posterior chambers.<sup>4,62</sup> The presence of a worm in or around the eye is frequently accompanied by swelling or edema of the eyelid and face (Figs. 101-3 and 101-4) and a sharp stinging or burning sensation. Worms located in the retina and anterior or posterior chamber of the eye are frequently recognized by the patient because of blurred vision and pain in or behind the eye. In some cases, there is no inflammation, blurred vision, or swollen lids. In general, reports of a worm in the connective tissues around the eye have been diagnosed as *Loa loa* or a zoonotic *Dirofilaria* species. Reports of a worm in the chamber of the eye often have been attributed to natural human filariae such as *Wuchereria bancrofti*, *L. loa*, or *Brugia malayi*. However, zoonotic infections due to *Dirofilaria* (*D. repens*, *D. immitis*), *Loaina*, *Dipetalonema*-like worms, *Brugia ceylonensis*, and *Onchocerca* have been described.<sup>23,41,55</sup> Many times, worms around or in the eye are recovered free from the tissues (Fig. 101-5), while occasionally those in the eye can either be extracted by irrigation-aspiration<sup>72</sup> or destroyed in situ using photocoagulation.<sup>73</sup>

**FIGURE 101-4** Coronal CT scan of the same patient as in Figure 101-3, demonstrating a discrete soft tissue mass without bony or intraorbital involvement. (From Kersten RC, Locastro AJ, Eberhard ML, et al: Periorbital dirofilariasis. *Ophthalmic Plast Reconstr Surg* 10:293–296, 1994.)

**FIGURE 101-5** Male *Dirofilaria tenuis* worm removed intact from the conjunctiva of a patient in the United States. Scale is in millimeters.

### Lung Infections

The second most common finding associated with zoonotic filarial infections is discrete lesions in the lung parenchyma resulting in very well-circumscribed, circular nodules (Figs. 101-6 through 101-8) that on radiographs appear as coin lesions.<sup>4,62</sup> These lesions are due most often to *D. immitis* but can be caused by *Brugia*-like worms.<sup>15</sup> There is a tendency for these nodules to be solitary and somewhat larger than those due to subcutaneous dirofilariasis. There are cases of multiple nodules<sup>74</sup> as well as reports of transient nodules, suggesting that human infections are much more common than thought.<sup>75</sup> Occasionally, these nodules are reported to be calcified.<sup>76</sup> Again, as in the case of subcutaneous dirofilariasis, patients with a lung nodule due to *D. immitis* are generally not in bad health, and it is not unusual for the lesions

**FIGURE 101-6** Radiograph showing a solitary, subpleural nodule (coin lesion) of the upper lobe of the right lung due to *Dirofilaria* infections. (From Pampiglione S, Canestri Trotti G, Rivasi F: Human dirofilariasis due to *Dirofilaria* [*Nochtiella*] *repens*: A review of world literature. *Parassitologia* 37:149–193, 1995.)

**FIGURE 101-7** CT scan of a solitary nodule in the left lung due to *Dirofilaria immitis* infection. (From Pampiglione S, Canestri Trotti G, Rivasi F: Human dirofilariasis due to *Dirofilaria [Nochtiella] repens*: A review of world literature. *Parassitologia* 37:149–193, 1995.)

to be detected on chest film as part of a routine physical examination. Over 50% of these patients are asymptomatic, although there are some reports of chest pain, low-grade fever, cough, and malaise. Eosinophilia may or may not be a remarkable clinical feature. In direct contrast to subcutaneous dirofilariasis, pulmonary dirofilariasis is almost always confused initially with a malignancy. A large number of reports have addressed the problem of zoonotic filarial infections mimicking pseudotumor or carcinomas, and issues related to differential diagnosis.<sup>77–83</sup> Once the lesion is removed, histologic examination reveals its true nature (Fig. 101-9), and the concern of both clinician and patient can be allayed.

### Lymphatic Infections

The location of zoonotic filariae in the lymphatics leads to the classic presentation of a tender, swollen lymph node

**FIGURE 101-9** Panoramic view of a histologic section of a classic coin lesion in the lung caused by *Dirofilaria immitis* infection. Some normal lung tissue is evident at the lower right-hand corner of the section, and several sections of a worm are evident (arrow). Note the well-circumscribed nature of this lesion, which measures approximately 12 mm in diameter. (H&E stain.)

(Fig. 101-10). Although zoonotic *Brugia* infections have been reported from a variety of anatomic locations, the three most common sites are the neck region, groin, and axillary region. These sites and others, such as the breast, reflect the prominent lymph nodes and channels that are found in these sites. The main presenting symptom is an enlarged, painful regional node of one to several weeks' duration. This finding frequently leads to an initial diagnosis of lymphoma or other malignancy. Eosinophilia may or may not be a presenting feature, and occasionally the enlarged node may not be tender. Histologically, the overall presentation is one of a hyperplastic node with a focal granulomatous reaction. The location of worms in a patent lymph channel is occasionally evident (Fig. 101-11), but in more advanced cases, the normal structural architecture of the lymph canal is lost in the inflammatory reaction (Fig. 101-12). These differences undoubtedly reflect

**FIGURE 101-8** Infarcted lesion in the lung (coin lesion) due to *Dirofilaria immitis* infection.

**FIGURE 101-10** Clinical photograph of an enlarged retroauricular lymph node (arrow) in a patient with a zoonotic *Brugia* infection. (From Kozek WJ, Reyes MA, Ehrman J, et al: Enzootic *Brugia* infection in a two-year-old Colombian girl. *Am J Trop Med Hyg* 33:65–69, 1984.)

**FIGURE 101-11** Histologic section of a lymph node from a case of zoonotic *Brugia* infection illustrating multiple sections of a worm in lymph channels. Scale bar = 200  $\mu$ m. (H&E stain.) (From Eberhard ML, DeMeester LJ, Martin BW, et al: Zoonotic *Brugia* infection in western Michigan. *Am J Surg Pathol* 17:1058–1061, 1993.)

both the condition of the worm (i.e., alive or dead) and the duration of the host response. Some nodules are removed in a much more acute stage than others. Because of the small size of these worms, it may be necessary to examine numerous sections before the worm is encountered.

### Microfilarial Infections

The detection of microfilariae ascribed to zoonotic filarial infections has not been correlated with clinical symptoms or signs in most cases, although there was clear central nervous system (CNS) involvement in human cases of *Meningonema peruzzii*,<sup>43</sup> and classic signs of lymphatic filariasis, including lymphedema, were noted in a case of zoonotic *Brugia* infection.<sup>34</sup>

### PATHOGENESIS AND IMMUNITY

The pathogenesis of zoonotic filariasis is one of localized foreign body reaction around a dead or dying parasite. On the basis of the size of worms seen in these cases and our understanding of the life history of some of these filariae in

**FIGURE 101-12** Histologic section of a lymph node from a zoonotic *Brugia* infection in which the lymph channel has been obliterated around the worm (arrow). Scale bar = 200  $\mu$ m. (H&E stain.)

their natural or experimental hosts, these represent infections of a month to many months' duration. More often than not, these infections are asymptomatic until just prior to the detection of the inflammatory nodule surrounding the worm. Some zoonotic infections, especially those caused by *Dirofilaria* and *Onchocerca*, may represent 6 months or more of asymptomatic growth and wandering by the developing worm. It is believed that only upon the impending death of the worm does a marked tissue reaction occur (an exception may be seen in worms that make their way to the tissues surrounding the eyes). Whether the host's response precedes and is responsible for killing the worm, or whether the worm dies because of physiologic incompatibility followed by host reaction to a moribund parasite, is unclear. The fact that many of these zoonotic infections persist asymptotically for appreciable periods of time suggests that the latter is the case.

Limited studies indicate that the human host produces antibodies directed at the parasite, and that these antifilarial antibodies can be detected in serum samples. In several cases of zoonotic *Brugia* infections, isotype-specific, antifilarial antibodies, as determined by an enzyme-linked immunosorbent assay (ELISA) using adult *Brugia* antigens, have demonstrated elevated responses that markedly diminish by 3 months postsurgery.<sup>39,40</sup> Various serologic assays have also been developed to detect *Dirofilaria* infections.<sup>84–90</sup> These assays, although frequently not able to distinguish between different types of infections, could clearly be helpful in suspected cases when no worm was observed in the biopsy but a suggestive granulomatous reaction was present, and in conducting sero-epidemiologic surveys. It has been suggested that zoonotic filarial infections result in immunopathologic reactions, such as arthritis.<sup>91</sup>

### DIAGNOSIS

The diagnosis of zoonotic filarial infections, for the foreseeable future, will continue to be the recognition and accurate identification of these parasites in excised or biopsy histologic sections.<sup>92</sup> This is not to say that good serologic assays would not play a vital role in diagnosis and management. However, because zoonotic filarial infections are constituted of any number of different species, serologic assays that are genus-specific rather than species-specific would be much more valuable as screening tools.

Diagnosis of the genus (and species) of filaria causing the infection is best accomplished by study of the morphologic features seen in tissue sections. Occasionally, intact worms are removed, particularly from in or around the eye, and these can usually be tentatively identified based on comparison with recognized species found in the area where the patient is believed to have acquired the infection.

Location of the lesion containing the worm can frequently provide some guidance in identifying the worm. For instance, a worm associated with the lymphatic system has a high probability of being a zoonotic *Brugia* infection, while the location of a worm in a coin lesion in the lung is likely to be *D. immitis*. However, diagnosing zoonotic filarial infections based solely on the location of the lesion is sure to result in many incorrect determinations. The morphology of the worm provides a much greater degree of accuracy (sensitivity) than does the location of the lesion and ensures that a worm in an unusual location is not misdiagnosed.

**FIGURE 101-13** High-power photomicrograph of a section of a female *Dirofilaria tenuis* from the same case as illustrated in Figure 101-1. This section clearly illustrates the nature of the thick cuticle with numerous external ridges and two internal lateral ridges (arrows) in the region of the lateral chords. Tall, heavy musculature, prominent lateral chords (asterisks), two uterine tubes, and a section of intestine are also evident. Scale bar = 50  $\mu$ m. (H&E stain.)

The diagnosis of zoonotic filarial infections is almost always made from stained tissue sections, and there are morphologic features that allow placement of worms into several broad groups.<sup>62,93,94</sup> These are discussed briefly in the following sections.

### *Dirofilaria*

By far the most common zoonotic infections encountered are caused by species of *Dirofilaria*. Three species are believed to account for the vast majority of recognized cases. *D. immitis*, the dog heartworm, has a nearly cosmopolitan distribution that is continuing to expand; *D. repens* infects dogs and cats in Europe, Africa, Southeast Asia, and possibly elsewhere; and *D. tenuis* is a natural parasite of raccoons in North America. Other species reported from humans include *D. striata* of wildcats in North and South America, and *D. ursi*, which parasitizes bears in North America and Japan. A vast number of other dirofilariæ exist, and all probably hold zoonotic potential.

**FIGURE 101-14** High-power photomicrograph of a section of a female *Dirofilaria tenuis* from the case illustrated in Figure 101-3. Although this worm is moribund and has undergone considerable degeneration, the thick cuticle with external ridging, heavy musculature, two uterine reproductive tubes, and a single digestive tube are still evident. Scale bar = 50  $\mu$ m. (H&E stain.)

**FIGURE 101-15** Photomicrograph of the coiled *Dirofilaria immitis* worm seen in Figure 101-9. At this magnification, several features of the worm are evident, including the thick cuticle and heavy musculature. Scale bar = 200  $\mu$ m. (H&E stain.)

*Dirofilaria* worms have several consistent features that are recognizable in sections. Generally, they are relatively large worms, up to 400 or 500 mm in diameter; they have a thick cuticle, which, with the exception of *D. immitis* and *D. striata*, has prominent longitudinal ridges; and the musculature is prominent, with numerous muscle cells that extend far into the body cavity (Figs. 101-13 through 101-18). The number

**FIGURE 101-16** High-power photomicrograph of the worm seen in Figure 101-15. At this higher magnification, it is evident that the worm is moribund and has undergone considerable degeneration. The cuticle is considerably swollen and thickened and has a smooth outer surface, and remnants of the heavy musculature are evident. Scale bar = 50  $\mu$ m. (H&E stain.)

**FIGURE 101-17** Low-power view of the cuticular surface of a *Dirofilaria repens* removed intact from the tissues, illustrating the beaded ridges that run longitudinally along the worm. Scale bar = 50  $\mu\text{m}$ .

and shape of the cuticular ridging can be useful in separating species, as can the absence of ridges. It should be noted here, although true for all zoonotic filarial infections, that size can be a very useful feature in the determination of possible species. However, one must also use caution, as many of the worms removed in these cases represent immature worms, which makes size comparisons difficult. There are also notable exceptions, such as *D. ursi*-like worms, which, when seen in human tissue, are much smaller than other dirofilariae but still have typical *Dirofilaria* features (ridged cuticle, etc.).

### **Brugia**

The recognition of small filariae in close association with lymph nodes or lymph vessels, or on rare occasions

**FIGURE 101-19** High-power view of a coiled female *Brugia* worm in a lymph channel, illustrating the small size of the worm, the thin cuticle, and the small number of low muscle cells per quadrant. Scale bar = 25  $\mu\text{m}$ . (H&E stain.)

the eye, would be suggestive of infection with a zoonotic *Brugia* species (see Figs. 101-10 through 101-12). The species involved in the reported human cases have not been established. A number of species have been described from various animals; in the United States we recognize two species, *B. beaveri* of the raccoon and *B. leporis* of rabbits; from South America, *B. guyanensis* of the coatimundi; *B. tupaia* of tree shrews and *B. pahangi* in dogs, cats, slow loris, leaf monkeys, and wildcats from Malaysia; *B. patei* of dogs, cats, wildcats, and bush babies from Africa; and *B. ceylonensis* from dogs and *B. buckleyi* from hares in Sri Lanka.

In section, zoonotic *Brugia* are small worms, almost always less than 150  $\mu\text{m}$  and occasionally less than 50  $\mu\text{m}$  in diameter. The cuticle is relatively thin but frequently thickens over the

**FIGURE 101-18** Cross section of an unstained *Dirofilaria repens* (in glycerin), illustrating the typical *Dirofilaria* anatomy. Evident is the thick, multilayered cuticle with external ridging (arrows), the thin inconspicuous hypodermal tissue that greatly expands in the area of the lateral chords (arrowheads), and the tall, heavy muscle cells that are composed of a narrow, basal, fibrillar, contractile portion (large asterisk) and a shorter cytoplasmic portion (small asterisk). Scale bar = 50  $\mu\text{m}$ .

**FIGURE 101-20** Low-power view of connective tissue containing three sections of a female *Onchocerca* species from a case of zoonotic human infection. The coiled nature of the worm, the thick cuticle, and ridging on the surface of the cuticle are evident. Scale bar = 200  $\mu\text{m}$ . (H&E stain.) (From Ali-Khan Z: Tissue pathology and comparative microanatomy of *Onchocerca* from a resident of Ontario and other enzootic *Onchocerca* species from Canada and the U.S.A. Ann Trop Med Parasitol 71:470–482, 1977.)

**FIGURE 101-21** Higher magnification of the worm seen in Figure 101-20, illustrating the nature of the cuticle, including external ridges, internal striae, and uneven thickness. Scale bar = 50  $\mu$ m. (H&E stain.) (From Ali-Khan Z: Tissue pathology and comparative microanatomy of *Onchocerca* from a resident of Ontario and other enzootic *Onchocerca* species from Canada and the U.S.A. Ann Trop Med Parasitol 71:470–482, 1977.)

**FIGURE 101-22** Higher magnification of a cross section of the female *Onchocerca* species seen in Figure 101-20, illustrating the typical features seen in zoonotic infections. The cuticle is thick throughout, but much thicker over the upper part of the worm as a result of an outer ridge. The muscle cells are few per quadrant and weak in nature; they are appreciably taller in the ventral hemisphere, seen here in the lower half of the worm. The hypodermal tissue is most evident in the region of the lateral chords. Two paired uteri are evident, as is the small intestine, which lies to the left. Scale bar = 50  $\mu$ m. (H&E stain.) (From Ali-Khan Z: Tissue pathology and comparative microanatomy of *Onchocerca* from a resident of Ontario and other enzootic *Onchocerca* species from Canada and the U.S.A. Ann Trop Med Parasitol 71:470–482, 1977.)

**FIGURE 101-23** Unstained, cleared section of body wall of *Onchocerca stilesi*, a natural parasite of the ligaments of the legs of cattle in the United States, illustrating the external ridging (arrow) and internal striae (asterisks) in the cuticle. Compare the stained section illustrated in Figure 101-24. Scale bar = 15  $\mu$ m.

lateral chords, and the muscle cells are few in number, flat, and broad, and do not extend far into the body cavity (Fig. 101-19).

### *Onchocerca*

The number of described *Onchocerca* species that might result in zoonotic infections in humans is too great to list here, but the genus is cosmopolitan, and normal animal hosts include a wide range of ungulates, including cattle, horses, camels, various antelope, deer, and sheep. *Onchocerca* species have a predilection for residing in or near connective tissues in their natural hosts, and this has been the case in the majority of zoonotic infections as well. Two cases involving the eye have been reported,<sup>23,26</sup> and there is at least one additional unpublished case of *Onchocerca* being recovered from the eye.

In sections (Figs. 101-20 through 101-24), *Onchocerca* have several prominent features including, in longitudinal section, a cuticle that bears external ridges and internal striae, and in transverse section, a thick cuticle that is often unevenly thickened; prominent hypodermal tissue not restricted to the lateral chords; and few muscle cells per quadrant that are distinctive in appearance, being atrophied and wispy. Because of the extreme length of female worms and their characteristic coiling, it is not unusual to see multiple sections of worm in a single tissue section.

**FIGURE 101-24** High-power photomicrograph of a longitudinal section of a female *Onchocerca stilesi*. This trichrome-stained section illustrates the characteristic features of the cuticle useful in identifying zoonotic onchocercal infections. The outer ridges and inner striae illustrated in Figure 101-23 are evident. Sections of uterus with developing microfilariae also are evident. Scale bar = 15  $\mu$ m.

### *Dipetalonema*-like

Zoonotic filarial infections that do not readily fall into the preceding categories are frequently referred to as *Dipetalonema*-like. Generally, these worms are small and have been reported from several anatomic locations, including the eye and subcutaneous tissue. A number of these cases have resulted in recovery of nearly intact worms from the eye.<sup>55</sup> The morphologic features of *Dipetalonema*-like worms in tissue are nondescript and include small size, the presence of a relatively thin, smooth cuticle, and weak musculature (see Fig. 101-20). Assigning a definitive identification to these specimens has been difficult owing in part to their immature state of development and further complicated by the large number of described species and the recognition that there may be a great number of as yet unrecognized species. This process is confounded by our lack of recognition of distinctive morphologic features of many worms in histologic section.

Interestingly, one report described recovery of microfilariae similar to *Mansonella interstitium* of squirrels from the blood of a 12-year-old child from Alabama, indicating that at least one adult male and female worm were present.<sup>48</sup>

### Zoonotic Filariae of Uncertain Origin (or Incompletely Described Zoonotic Infections)

There are numerous other reports of zoonotic filarial infections in humans, some of which represent single case reports, while in others only microfilariae have been recovered with no description of the accompanying adult worm. These are briefly discussed as follows:

In 1932, Owen and Hennessey<sup>95</sup> first noted the occurrence of 33 cases of an unusual presentation of filariae located on the conjunctiva of persons living in Uganda. This account reported the presence of small (approximately 2 mm in diameter), yellow nodules in which were remnants of dead filarial worms. The authors referred to these cases as “bung-eye” or “bulge-eye.” In 1973, Poltera<sup>96</sup> reviewed an additional 40 cases and provided further epidemiologic and clinical information, and he concluded that the worms were *Loa*. However, morphology of the worms does not support the diagnosis of loiasis. Baird and colleagues<sup>97</sup> reviewed eight cases of bung-eye (Fig. 101-25) collected from several countries in Africa, and concluded that the majority of cases were caused by aberrant localization of *Mansonella perstans* (Fig. 101-26). This determination suggests that these infections were not zoonotic but rather common human infections in an uncommon location. However, a final decision on the identity of these worms awaits a better understanding of the microanatomy of the genus *Mansonella*, which contains a number of species that infect humans as well as animals. Whether bung-eye is truly a zoonotic infection cannot be established at this time. What is clearer now is that bung-eye is not restricted geographically to Uganda but occurs in a much wider area that, for all practical considerations, appears to overlap with the range of several of the human filariae, including *M. perstans* and *M. streptocerca*.

In 1968, Dukes and colleagues<sup>43</sup> described two cases of microfilariae in the CSF from residents of then Rhodesia (now Zambia and Zimbabwe). The authors attributed the infections to *M. perstans* and provided detailed clinical descriptions. In 1973, Orihel and Esslinger<sup>98</sup> described a new

**FIGURE 101-25** Photograph showing three small nodules (arrow) in the conjunctiva of a Ugandan, typical of those seen in cases of bung-eye. (From Baird JK, Neafie RC, Connor DH, et al: Nodules in the conjunctiva, bung-eye, and bulge-eye in Africa caused by *Mansonella perstans*. Am J Trop Med Hyg 38:553–557, 1988.)

filarial parasite, *Meningonema peruzzii*, from the CNS of African monkeys. The microfilariae of *M. peruzzii*, although sheathed, resemble *Mansonella perstans* microfilariae to a great extent. In that same year, Orihel,<sup>44</sup> who reviewed original material from the previous human cases reported by Dukes and associates was able to demonstrate a sheath on the microfilariae, and concluded that these constituted zoonotic infections due to *M. peruzzii*. Because of the anatomic location of the adult worms in the subarachnoid spaces associated with the meninges, it is highly unlikely that these worms will be encountered routinely in tissue sections. However, clinicians and laboratorians must be alert to the presence of microfilariae in CSF (and possibly blood) and to the morphologic features

**FIGURE 101-26** High-power photomicrograph of a worm, identified as *Mansonella perstans*, seen in sections of a nodule removed from a case of bung-eye in Uganda. The morphologic features of the parasite include a thin cuticle, which is thicker over the lateral chords (arrowheads); numerous muscle cells, which are low and do not extend far into the body cavity; paired uteri (large asterisks); and a very thin walled intestine (small asterisk). Scale bar = 20  $\mu$ m. (H&E stain.) (From Baird JK, Neafie RC, Connor DH, et al: Nodules in the conjunctiva, bung-eye, and bulge-eye in Africa caused by *Mansonella perstans*. Am J Trop Med Hyg 38:553–557, 1988.)

of the parasite, including the presence of a sheath. A report of this filaria in humans further confirms its zoonotic potential and suggests that additional cases will be uncovered.<sup>99</sup>

An unusual microfilaria with a marked clear region in the posterior body was described by Fain<sup>45</sup> in 1974 from some 52 inhabitants of several villages in Zaire; the microfilaria was named *Dipetalonema semiclarum*.<sup>45</sup> *D. semiclarum* resembles *M. perstans* but differs by having, in addition to the clear space in the posterior half of the body, a much longer cephalic space. The adult stage has not been recovered and described, but the microfilaria does not correspond to any recognized species reported from animals of that region of Africa.

In 1980, an unrecognized microfilaria was reported from the blood of American Indians living in the Orinoco River basin in Venezuela.<sup>46</sup> I was given the name *Microfilaria bolivarensis*. The microfilaria superficially resembles that of *Onchocerca volvulus* but is smaller and stouter and has a shorter cephalic space and less compact nuclear column. Infections were commonly mixed with *Mansonella ozzardi*, which occurs frequently in that area. The microfilaria has not been reported since.

Richard-Lenoble and colleagues<sup>42</sup> reported in 1982 the occurrence of microfilariae indistinguishable from *Mansonella rhodhaini* in 14 inhabitants of Gabon. This is a natural parasite of chimpanzees, and the microfilariae measure more than 300  $\mu\text{m}$  in length by only 2 to 3  $\mu\text{m}$  in diameter, making them clearly distinct from either *Onchocerca volvulus* or *Mansonella streptocerca*.

## TREATMENT AND PROGNOSIS

Treatment of zoonotic filarial infections almost always involves surgical removal of the worm or lesion containing the parasite. Frequently, the correct diagnosis is not made until after examination of the specimen or histologic section reveals the identification. However, since the most cases appear to involve only a single worm, surgical removal is curative. Although generally not indicated, a course of diethylcarbamazine or ivermectin would seem to offer the greatest likelihood of symptomatic treatment.

The prognosis in most cases is good. Many worms probably die and are absorbed without any clinical signs or symptoms. In those cases in which a marked tissue reaction draws attention to the presence of a foreign body, the lesion, as noted, is frequently removed surgically. If the host tissue reaction were left to run its course without surgical intervention, the parasite would eventually die and be resolved and the inflammatory lesion would subside over time. This scenario would be true for worms in almost all locations, except worms inside the eye (anterior or posterior chamber, retina). In this location, the physical damage caused by the worm itself, as well as a pronounced inflammatory reaction, could result in serious, permanent damage and loss of visual acuity.

## PREVENTION AND CONTROL

Prevention and control of zoonotic filarial infections are difficult tasks, further complicated by the insect intermediate host. The surest way to prevent zoonotic filarial infections is to protect oneself from the bite of potentially infected insect vectors. This is easier stated than accomplished, especially given the wide range of potential vectors. Because the majority of filariae that are known to cause zoonotic infections are

transmitted by various mosquito species, the greatest risk is through mosquito bites. Protective clothing, use of insect repellents, household screening, and behavior modification geared toward avoidance of insect bites would provide some degree of protection.

Control of zoonotic filarial infections is even more challenging. Clearly, efforts directed at reducing mosquito or other biting insect populations would significantly reduce the risk of exposure. Because of flight ranges, however, these efforts would need to be coordinated and sustained at the community level or higher. Local government efforts directed at mosquito abatement probably indirectly reduce the overall risk of zoonotic filarial infection. Of the species of filariae that are recognized to cause zoonotic infections, only the dog heartworm, *D. immitis*, occurs exclusively in a domestic pet population (although *D. repens* can be a common infection in dogs as well). Putting a household pet dog on heartworm preventive treatment may well reduce the likelihood of acquiring infection from one's own pet, but unless every dog (and wild canid) in the area is treated, a potential risk still exists. However, until there is better understanding of why some individuals exposed to zoonotic filariae develop infection while most others do not, it will be difficult to develop comprehensive prevention and control strategies.

# Dracunculiasis

ERNESTO RUIZ-TIBEN  
DONALD R. HOPKINS

## INTRODUCTION

Guinea worm disease (dracunculiasis), caused by the nematode parasite *Dracunculus medinensis*, is a disabling disease of rural people in parts of 11 countries in Africa.<sup>1,2</sup> Other synonyms for the infection include dracontiasis and dracunculosis. Salient characteristics of this infection are that it manifests by 2-to-3 foot (~1 meter) long worms emerging directly through a lesion on the skin and has an enormous adverse impact on school attendance and agricultural production. It is also close to being completely eradicated.

## AGENT

*Dracunculus medinensis* has been known since at least ancient Egypt. Because differentiation between species of *Dracunculus* requires morphological examination of adult male worms (which are seldom available), efforts are underway to

map the genome of the Guinea worm's DNA in order to ascertain this parasite's species more precisely and reliably. Although there are several known zoonotic species of *Dracunculus*, only *medinensis* is specific to humans. The life cycle of the parasite was first fully described by Alexei Fedechenko in 1870.<sup>3</sup>

## EPIDEMIOLOGY

During the 19th and 20th centuries, dracunculiasis was common in much of southern Asia, and in North, West, and East Africa. When the Dracunculiasis Eradication Program was getting underway in 1986, an estimated 3.5 million cases still occurred in India, Pakistan, Yemen, and 17 African countries.<sup>4</sup> By 2004, fewer than 16,000 cases were reported in the 11 remaining endemic countries of East and West Africa; Asia was already free of the disease.

People become infected when they drink water containing tiny freshwater crustaceans called copepods or "water fleas," which act as intermediate hosts and harbor infective larvae.<sup>5</sup> When the ingested copepods are killed by the digestive juices in the stomach, the larvae are released and move to the small intestine, where they penetrate the intestinal wall and migrate to the connective tissues of the thorax.<sup>5</sup> Male and female larvae mature and mate 60 to 90 days after infection. Over the next 10 to 14 months, gravid female worms mature, reaching lengths of 70 to 100 centimeters (2–3 feet), and slowly migrate to the surface of the body. On contact with fresh water, powerful contractions cause a loop of the worm's uterus to break and discharge a swarm of motile larvae. Contraction of the worm and discharge of larvae may be repeated if the lesion is again submerged in water, until the entire brood of larvae is discharged. Motile free-swimming larvae are ingested by copepods and mature in the body cavity in about 2 weeks.

Distribution of cases of dracunculiasis (Guinea worm disease) East and West Africa, January—November 2004 (provisional)

Stagnant sources of drinking water such as ponds, cisterns, pools in dried-up river beds, and shallow unprotected hand-dug wells commonly harbor populations of copepods and are the usual sites where infection is transmitted.

The disease's seasonality varies according to location. In endemic areas just below the Sahara Desert (e.g., Mauritania, Mali, Niger, Burkina Faso, southern Sudan, and Ethiopia), transmission usually peaks during the rainy season at mid-year (May to September). This is because stagnant surface sources of water are only present during the relatively brief rainy season in such areas. In areas near the Gulf of Guinea (e.g., Côte d'Ivoire, Ghana, Togo, Benin, and Nigeria), the disease peaks during the dry season, from October to March, when surface sources of drinking water are scarcest and most concentrated, in contrast to abundant surface water sources during the rest of the year. The seasonal emergence of the worm often coincides with harvest or planting seasons, and thus significantly affects agricultural productivity and school attendance.

## DISEASE

Infected persons remain asymptomatic for approximately a year after infection, when the mature female worm approaches the skin and forms a painful papule in the dermis. This papule can become a blister within 24 hours or may enlarge for several days before becoming a blister (Fig. 102-1A). Eventually the blister ruptures, exposing the worm (Fig. 102-1B). Shortly before the skin lesion forms, systemic symptoms may occur, including local erythema and urticarial rash with intense pruritus, nausea, diarrhea, and dizziness. Worms usually emerge from the lower extremities, but they can also emerge from any part of the body, including the head, upper extremities, buttocks, and genitalia. As the worm emerges through the skin lesion, the affected person pulls it out slowly and carefully (because of inflammation and pain), usually by winding a few centimeters of the worm each day on a small stick. This very painful process may last many weeks. Pain and other symptoms may lessen with the rupture of the blister, but at this

A

time pyogenic organisms invariably invade the superficial lesion and worm tract and aggravate the condition (Fig. 102-2). If the worm breaks during extraction, an intense inflammatory reaction occurs, with pain, swelling, and cellulitis along the worm tract. The reported period of incapacitation ranges from 2 to 16 weeks (average 8.5 weeks)<sup>6-18</sup> and more than half of a village's population may be affected at the same time. In addition to the blisters and skin lesions, the secondary bacterial infections usually exacerbate local inflammation and often lead to sepsis, abscesses, septic arthritis, contracture of muscles near joints, or even tetanus.

### **PATHOGENESIS AND IMMUNITY**

The symptoms produced by *Dracunculus* vary in the acute or chronic phases of the infection. The acute manifestations begin about 1 year after infection and are related to the release of the larvae into the water. The initial blister in the skin is accompanied by redness and induration and is usually preceded by slight fever and allergic symptoms. The lesion is found in 85% to 90% of cases on the lower extremities, including the ankle, or foot. The blistering lesion produces intense irritation and burning, inducing the patient to seek relief by immersing the affected limb in water, where the blister breaks, allowing the adult worm to discharge larvae into the water. The chronic manifestations are due to inflammation of the joints with clinical symptoms and signs of arthritis,<sup>19</sup> synovitis,<sup>20</sup> and muscle and tendon contractures with resultant ankylosis of the limb.<sup>21</sup> Migration of the worms to the retroperitoneum and from the retroperitoneum to the subcutaneous tissue in the leg sometimes results in aberrant (ectopic) locations of the worm such as in the pancreas,<sup>22</sup> lung,<sup>23</sup> periorbital tissues,<sup>24,25</sup> testis,<sup>26</sup> pericardium,<sup>27</sup> and the spinal cord, producing compression<sup>28,29</sup> as well as focal abscess formation.<sup>30</sup> Infected persons do not develop immunity.

### **DIAGNOSIS AND TREATMENT**

The diagnosis is indicated by the formation of the typical skin blister and emergence of the adult female worm. There is no

**FIGURE 102-2** Pyogenic organisms invade the superficial lesion and worm tract, aggravating the condition. (Courtesy of WHO Collaborating Center for Research, Training, and Eradication at the Centers for Disease Control and Prevention.)

curative drug or vaccine against dracunculiasis. Applying wet compresses to the lesion may relieve pain during the worm's emergence. Placing an occlusive bandage on the wound keeps it clean and may help prevent the patient from contaminating sources of drinking water. Oral medications to alleviate the associated pain and inflammation, and topical antiseptics or antibiotic ointment to minimize the risk of secondary bacterial infections, also help reduce inflammation and may permit removal of the worm by gentle traction over a number of days.

## CONTROL AND ERADICATION

Transmission of dracunculiasis is prevented by educating people about the origin of the disease, teaching them to filter drinking water through cloth to remove the copepods, and to never enter a source of drinking water (or allowing anyone else to do it) when a Guinea worm is emerging. The ideal means of prevention is the provision of safe sources of drinking water. Applications of ABATE larvicide in selected unsafe sources of drinking water to control copepod populations is another means of controlling transmission of the disease.

The global Dracunculiasis Eradication Program (DEP) began in 1981, when the Centers for Disease Control and Prevention (CDC)<sup>31</sup> proposed that eradication of dracunculiasis was an ideal indicator with which to measure the success of the International Drinking Water Supply and Sanitation Decade (1981–1990), since this disease is only transmitted via drinking water. That same year, the steering committee of the Decade adopted dracunculiasis eradication as a sub-goal of their efforts. The African ministers of health passed a resolution in 1988 calling for the eradication of dracunculiasis by 1995, and the World Health Assembly endorsed that mandate in 1991.<sup>32</sup> Since 1988, a growing number of agencies, organizations, companies, and other institutions have assisted national programs with their efforts to eradicate dracunculiasis. India began its own independent national dracunculiasis eradication program in 1983.

The strategy for dracunculiasis eradication includes three phases.<sup>33</sup> During Phase I, national programs conducted nationwide or areawide case searches to determine the locations of villages with endemic transmission and the numbers of cases, organized a national secretariat and a program structure at district and village levels, and developed a national plan of action. In Phase II, program staff and village-based health workers (village volunteers) were trained to implement interventions against transmission of the disease, conduct active village-based surveillance using case registers, provided health education to mobilize communities to action, provided cloth filters, and educated villagers on their care and proper use. During Phase III, when the incidence of disease has been reduced to fewer cases per year and halting transmission is imminent, surveillance is intensified to rapidly detect all persons with emerging worms (preferably before or within 24 hours of worm emergence) and to contain transmission from each case by providing care for the wounds, applying occlusive bandages, and counseling the patient not to enter sources of drinking water. In 2001, most national programs began offering persons with dracunculiasis the option of medical care at "case containment centers." When patients voluntarily attend such case containment centers, they are provided a small monetary or in-kind incentive for agreeing to stay at the center until each Guinea worm is successfully pulled out, medical care,

food, sanitation, and shelter. Care of the last cases of dracunculiasis at case containment centers or at established public health clinics permits patients to recover from their incapacitation much faster and allows the program to contain transmission from each emerging worm much more effectively. All other broad-based interventions continue to be employed until transmission is halted.

Attainment of eradication is not certified until the national program requests the World Health Organization (WHO) to validate the claim that no cases have occurred during 3 years since the last indigenous case, and an international certification team confirms that the surveillance system is sensitive and has not detected indigenous cases during the required 3-year period. An International Commission for the Certification of Dracunculiasis Eradication reviews the findings of the certification team and recommends to the WHO whether or not to certify the country free of dracunculiasis.<sup>34</sup>

As of 2004, the total number of reported cases of dracunculiasis had been reduced by more than 99% since 3.5 million cases were estimated in 1986. Nine of the 20 endemic countries have interrupted transmission of dracunculiasis, and 5 of the remaining countries with endemic disease reported less than 100 cases each. The number of villages reporting one or more cases outside of Sudan has dropped from greater than 23,000 to less than 2000. So far, India, Pakistan, Yemen, and Senegal are the only recently endemic countries that have been certified as dracunculiasis-free by WHO, in addition to 164 other countries.

The Sudan Guinea Worm Eradication Program began in 1992–1993 with a village-by-village search for cases in areas accessible to the government of Sudan. Many endemic areas of southern Sudan were inaccessible to the program because of the then 10-year-old civil war. The program accelerated its progress in 1995, including in rebel-held areas, under a 6-month "Guinea Worm Cease-Fire" that was negotiated between the two sides in the war by former U.S. President Jimmy Carter.<sup>35</sup> Sudan reported 50% or more of all cases of the disease each year from 1995 to 2003. Transmission of the disease has been interrupted in the northern states of Sudan; all of Sudan's cases are now in the southern states, where most of the fighting has occurred. A political settlement of the war was signed in January 2005. This will allow the global DEP to complete the eradication of the disease, which should be possible to achieve within about 5 years after the war ends.<sup>36</sup> Sudan is believed to have up to 8000 endemic villages, of which the national program had access to 6400 at the end of 2003.

# Toxocariasis and Larva Migrans Syndromes

THOMAS A. MOORE  
JAMES S. McCARTHY

## INTRODUCTION

Toxocariasis is the clinical term used to describe human infection with either the dog ascarid *Toxocara canis* or the feline ascarid *Toxocara cati*. As with other helminthic zoonoses, the infective larvae of these *Toxocara* species cannot mature into adults in the human host. Instead, the worms wander through tissues and organs in a vain attempt to find that which they need to mature into adults. The migration of these immature nematode larvae causes local and systemic inflammation, resulting in the “larva migrans” syndromes. Although human toxocariasis has been studied more intensively in Western countries, the disease has a global distribution, occurring in areas wherever dogs coexist with humans.

The clinical manifestations of toxocariasis (Table 103-1) are divided into visceral larva migrans (VLM) and ocular larva migrans (OLM). Subclinical infection is often referred to as covert toxocariasis. Cutaneous larva migrans, on the other hand, is most often caused by hookworms of domestic animals and is a widespread and well-recognized dermatologic problem in the tropics.

This chapter covers toxocariasis (including visceral and ocular larva migrans) and cutaneous larva migrans.

Other helminthic zoonoses that cause similar larva migrans syndromes (e.g., gnathostomiasis, angiostrongyliasis, and anisakiasis) are discussed elsewhere (see Chapters 105 and 106).

## AGENTS

*Toxocara* species are nematodes, taxonomically included within the order and family Ascaridida. The morphology of the adult worms resembles that of *Ascaris lumbricoides*, only they are much smaller: the males measure 4 to 6 cm long, females 6.5 to 10.0 cm long. The brown-colored eggs are almost spherical, with superficial pits, and are larger than *A. lumbricoides*, measuring 85  $\mu\text{m}$   $\times$  75  $\mu\text{m}$ .

In the dog, the life cycle of *T. canis* is similar to that of *A. lumbricoides* in humans, but with two important differences: The parasite can undergo developmental arrest within the definitive host, and vertical transmission occurs from infected pregnant bitches to their pups.<sup>1</sup>

Gravid adult female worms, which are generally found only in young puppies and lactating bitches, excrete up to 200,000 eggs per day in the feces of an infected dog. Freshly passed eggs are unembryonated and develop into infective, embryonated eggs over several weeks at optimum temperature (10°C to 35°C). Lower temperatures delay embryonation. Like other ascarid eggs, *Toxocara* eggs are hardy and relatively resistant to freezing, moisture, and extremes of pH<sup>2</sup> and retain their infectivity for months.<sup>3</sup> Unembryonated eggs shed in the winter can lie dormant until temperatures rise in the spring.

On the ground, the infective first-stage larvae within these unembryonated eggs molt twice to become third-stage juveniles. However, they do not shed their second-stage cuticle until after ingestion. Infection begins when these now-embryonated eggs are ingested. The eggs hatch in the duodenum; the larvae penetrate the intestinal wall and eventually reach the liver where they increase in size but do not molt. From the liver, the larvae travel to the heart and then to the lungs, where they molt into the fourth stage. In young dogs (under 6 months), the larvae travel from the lungs into the trachea where they are swallowed. The larvae undergo an additional molt in the stomach before maturing into adults in the intestine. Mating then results in release of unembryonated eggs, making the infection patent 60 to 90 days after egg ingestion. In older dogs (6 or more months), most infective juveniles do not go from lungs to the trachea but are transported from the lungs

**Table 103-1** Clinical Syndromes of Human Toxocariasis

Syndrome	Clinical Findings	Average Age	Infectious Dose	Incubation Period	Laboratory Findings	Toxocara Antibody Titer (ELISA)
Visceral larva migrans	Fever, hepatomegaly, asthma	5 yr	Moderate to high	Weeks to months	Eosinophilia, leukocytosis, elevated IgE	High
Ocular larva migrans	Visual disturbances, endophthalmitis, retinal granuloma	12 yr	Low	Months to years	Usually none	Low
Covert toxocariasis	Abdominal pain, gastrointestinal symptoms, weakness, pruritus	School age to adult	Low to moderate	Weeks to years	Eosinophilia and/or elevated IgE may be present	Low to moderate

to somatic tissues hematogenously. In adult dogs, none of the juveniles return to the intestine, but go to somatic tissues and remain in a state of arrested development for as long as 6 months. This migration to somatic tissue creates the conditions for transplacental and transmammary transmission to pups; latent somatic larvae are reactivated during each pregnancy and migrate either across the placenta to the fetal liver after the 45th day of gestation or to the mammary gland.<sup>4</sup> Larvae acquired in utero by the puppies remain as third-stage juveniles until birth, when they mature in the intestine of the pups. Puppies born with a patent infection shed large numbers of eggs from birth. In contrast, adult dogs excrete few eggs. Dogs born without infection can acquire the infection later by ingesting eggs from the soil or by ingesting embryonated eggs carried by transport hosts such as earthworms, ants, and other soil-dwelling invertebrates.

A wide variety of animals, including humans, can become infected with *T. canis* by ingesting embryonated eggs from contaminated soil, hands, or fomites. In these paratenic, or transport, hosts, the larvae follow a similar sequence of events as in an older, nonpregnant dog. The larvae do not develop to maturity, but migrate for months throughout host tissues before lodging within host tissues in a state of arrested development. The larvae do not encyst but remain exposed to the host environment, absorbing nutrients across the nematode cuticle. The larvae can survive in tissue for several years despite vigorous host immunologic responses to parasite antigens.<sup>5</sup>

Humans are paratenic hosts for *T. canis*. Paratenic hosts are transport hosts in which the larvae never develop into adult worms. The infection is acquired by ingesting *T. canis* embryonated eggs. Sources of these eggs are areas where dogs defecate, such as public parks.<sup>6</sup> Infections acquired by ingestion of raw snails and raw lamb have also been reported.

The cat roundworm, *T. cati*, has a life cycle similar to that of *T. canis* except that vertical transmission is due to lactation more than transplacental transmission. One report documents four cases of adult *T. cati* intestinal infection in children,<sup>7</sup> but in most cases humans are paratenic hosts. *T. cati* causes fewer cases of human infection than *T. canis*, probably because of the defecation patterns of cats, which make environmental infestation less frequent. Although other zoonotic nematodes may be responsible for some cases of visceral larva migrans, *Toxocara leonina*, another ascarid parasite of dogs and cats, has not been associated with human disease.

## EPIDEMIOLOGY

The ascarids *T. canis* and *T. cati* are ubiquitous parasites of dogs and cats, respectively, and occur in both temperate and warm climates. These parasites appear to have caused disease for millennia.<sup>8</sup> *T. canis* infection of dogs has been reported worldwide, and canine infection rates vary widely. Not surprisingly, environmental contamination of public grounds with *T. canis* eggs is also widespread.<sup>9–17</sup> Infected rodents may constitute a significant reservoir of *Toxocara* larvae.<sup>18</sup>

Toxocariasis in man is presumed to be contracted through the ingestion of eggs from contaminated soil; children with geophagia (pica) and contact with a litter of puppies appear to be particularly vulnerable.<sup>19</sup> Recent data suggest that dogs infected with *T. canis* may infect people by direct contact.<sup>20</sup> Additional risk factors include mental retardation requiring

institutionalization<sup>21</sup> and ingestion of infected meat<sup>22</sup> and raw liver from lamb<sup>23</sup> or chicken.<sup>24</sup>

Because toxocariasis does not become patent in humans, estimates of prevalence in humans depend on immunosurveys. These seroepidemiologic studies show wide differences depending on the population tested. The seroprevalence of toxocariasis in children aged 1 to 11 years in the United States, as measured by enzyme-linked immunosorbent assay, varies from approximately 4% to 8%,<sup>25</sup> with higher rates in Puerto Rico and the southeastern United States.<sup>26</sup> Even higher infection rates of 16% to 30% have been reported among socioeconomically disadvantaged African-American<sup>25</sup> and Hispanic<sup>27</sup> children. Similar rates have been reported in Europe.<sup>28,29</sup> The prevalence of human toxocariasis in the tropics is not well known, but is assumed to be significant since canine infection with *T. canis* is commonly found in these areas<sup>30,31</sup> and veterinary care is rare. Substantial rates of toxocariasis have been found among rural and jungle populations in tropical South America,<sup>32,33</sup> the Caribbean,<sup>34</sup> Southeast Asia,<sup>35</sup> and India.<sup>36</sup>

## DISEASE

### Visceral Larva Migrans

In 1952, Beaver and colleagues reported a series of children who presented with high circulating eosinophilia and suffered from severe, long-term, multisystem disease.<sup>37</sup> Examination of biopsy tissue revealed the causative agents as larvae of either *T. canis* or *T. cati*.

As classically described, the syndrome of VLM is characterized by eosinophilia, fever, and hepatomegaly.<sup>38</sup> It is most commonly seen in toddlers with a history of pica and an association with puppies. However, the spectrum of VLM also includes cough, wheezing, bronchopneumonia, and anemia. Although almost any organ can be affected, the liver is the most frequently involved, and hepatomegaly is a common finding. Occasionally the lesions may be mistaken for neoplastic metastases.<sup>39</sup> A minority of patients can develop splenomegaly or lymphadenopathy. Urticaria and subcutaneous nodules have been reported. Wheezing is a common presentation of VLM,<sup>40</sup> and severe asthma and hypereosinophilia can develop in intense infections.<sup>41</sup> Pulmonary infiltrates occur on chest radiographs, and toxocariasis can produce acute or chronic eosinophilic pneumonia,<sup>42,43</sup> occasionally progressing to respiratory failure.<sup>44</sup> Monoarthritis, panniculitis, and other rheumatologic manifestations can develop.<sup>45</sup>

Albeit rare, direct invasion of the central nervous system by *T. canis* larvae can occur, resulting in a variety of neurologic disorders including eosinophilic meningitis,<sup>46</sup> meningoencephalitis,<sup>47,48</sup> seizures,<sup>49</sup> static encephalopathy,<sup>50</sup> arachnoiditis,<sup>51</sup> solitary brain lesions,<sup>52</sup> and myelitis.<sup>53,54</sup> Cardiac involvement with *T. canis* rarely occurs, but can be serious.<sup>55,56</sup>

### Ocular Larva Migrans

Nematode endophthalmitis was first recognized in 1950 in a series of eyes enucleated for presumed neuroblastoma.<sup>57</sup> Ocular involvement with *T. canis* larvae results in the clinically distinct syndrome OLM. Patients with OLM tend to be older

# Visceral larva migrans (*Toxocara canis*)\*

\* Although VLM is characteristic for *T. canis*, it may occur with *T. cati* from cats and the general term "larva migrans" has referred to other non-human nematodes infecting humans, such as, *Baylisascaris procyonis*, a raccoon ascarid whose larvae migrate to brain and cause eosinophilic meningoencephalitis in young children.

children without evidence of other organ involvement, suggesting an alternative pathogenesis.<sup>5</sup> *T. canis* larvae that migrate to the eye become trapped, resulting in an eosinophilic inflammatory mass. The syndrome takes several weeks to become clinically apparent, but the patients are typically older children that present with unilateral visual deficits, ocular pain, leukocoria, or strabismus.<sup>58</sup> The retinal lesion most commonly presents as a solid tumor often at or near the macula. In the early stages, it is raised above the level of the retina

and closely mimics a retinoblastoma (Fig. 103-1). After the acute phase has subsided, the lesion remains a well-defined circumscribed area of retinal degeneration. Strabismus due to macular damage is often the presenting symptom. Low-grade iridocyclitis with posterior synechiae may develop and progress to endophthalmitis and retinal detachment.<sup>59</sup> Posterior and peripheral retinochoroiditis as well as optic papillitis have also been reported.<sup>60</sup> The inflammatory response created by ocular involvement may result in epiretinal membrane

**FIGURE 103-1** Granulomatous lesion of the liver due to visceral larva migrans.

formation and traction retinal detachment. In contrast to VLM, hypereosinophilia, hepatomegaly, and pulmonary symptoms are typically absent in OLM.

### Covert Toxocariasis

Patients with serologic evidence of toxocariasis who have mild or no symptoms of infection fall into the category “covert” or “occult” toxocariasis. The development and commercial availability of serologic tests for toxocariasis has facilitated the identification of these individuals.<sup>27</sup> To minimize confusion, a new category has been recently proposed for patients with asymptomatic infection.<sup>61</sup> Children with hepatomegaly, cough, sleep disturbance, abdominal pain, and headache are more likely to have elevated toxocaral antibody titers.<sup>62</sup> Eosinophilia was identified in only a slight majority of the cases and, when present, was mild. Recurrent abdominal pain is often the sole presenting complaint.<sup>63</sup> Less common findings include anorexia, fever, and cervical adenitis. Covert toxocariasis occurs in adults as well, as noted in an endemic focus in the French Pyrenees: Patients demonstrated nonspecific manifestations of weakness, pruritus, rash, difficulty breathing, and abdominal pain.<sup>64</sup> An apparently robust association exists between *Toxocara* seropositivity and allergic asthma and recurrent bronchitis,<sup>65</sup> although this correlation has not been verified in other settings.<sup>66</sup> The impact of VLM on behavior and learning disorders is unknown but a link has been suggested in murine models<sup>67</sup> and evidence points to a correlation.<sup>19</sup>

The prevalence of *Toxocara* seropositivity suggests that most human infections are asymptomatic. Indeed, most children with mild eosinophilia and antibodies to *T. canis* do not appear to develop clinically apparent sequelae when evaluated for up to 7 years.<sup>68</sup>

### PATHOGENESIS AND IMMUNOLOGY

The mucinous surface coat of *T. canis* larvae is a dynamic structure that turns over quite rapidly and generates large quantities of glycosylated excretory-secretory proteins.<sup>69,70</sup> Many of these proteins constitute a family of highly antigenic mucins<sup>71</sup> that, like most other tissue helminth antigens, induce a Th2-type CD4+ cellular immune response characterized by

the production of interleukin (IL)-4 that promotes eosinophilia and the production of immunoglobulin E (IgE).<sup>72</sup> However, the recruited eosinophils adhere to a membranous layer that is frequently detached from the larval epicuticle, allowing the larvae to largely evade the immune response elicited by these antigens.<sup>73</sup> In murine models of infection, the dominant cytokine produced is IL-5,<sup>74</sup> which plays a major role in the induction of eosinophilia; however, overproduction of IL-5 in transgenic mice does not significantly inhibit the life cycle of *T. canis* larvae, suggesting an alternative method by which the parasites are cleared.<sup>75</sup> Investigation into other molecular aspects of the parasite promise further insight into the pathophysiology of toxocariasis.<sup>76</sup>

*T. canis* larvae elicit both a humoral and cellular response in humans. Tissue damage is due to the host inflammatory reaction more than the infection itself. In both experimental and natural infections, *Toxocara* larval antigens induce granulomatous inflammation with eosinophils, histiocytes, and fibrous tissue (Fig. 103-2). Although the granulomas commonly develop where the larvae have come to rest, they do not always contain the larvae themselves. The granulomas are found most often in the liver, but they may be found in any tissue, including the lungs, brain, and eyes. These eosinophil-mediated granulomatous responses are almost exclusively responsible for the clinical manifestations of toxocariasis; however, it is not clear what factors are responsible for the development of OLM, VLM, or covert toxocariasis. It has been proposed<sup>5</sup> that parasite load is the key determinant of disease severity. Specifically, ingestion of lower doses of infective eggs is more likely to result in OLM or asymptomatic infection, whereas VLM is associated with a larger inoculum.

### DIAGNOSIS

Like most parasitic diseases, the diagnosis of toxocariasis is made initially on clinical grounds, with confirmatory testing playing a secondary role. The diagnosis should be entertained when a child is found to have eosinophilia (absolute eosinophil count greater than 450 eosinophils/mm<sup>3</sup>) and leukocytosis, especially when accompanied by hepatomegaly, fever, or wheezing. Exposure to dogs, particularly puppies, is an additional clue to the diagnosis. In the absence of hepatomegaly,

**FIGURE 103-2** Retinal lesion of ocular larva migrans.

the symptoms and signs of VLM mimic tropical pulmonary eosinophilia, as well as the larva migrans syndromes seen with ascariasis, hookworm infection, and strongyloidiasis (see Chapters 109–111).

Other laboratory findings include hypergammaglobulinemia and elevated isohemagglutinin titers to A and B blood group antigens. The latter develop as a result of cross-reaction to parasite antigens. Radiographic imaging of involved organs using ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) can identify focal lesions. If biopsied, these lesions will show granulomatous inflammation; however, larvae are not always found within the granulomas. Biopsy is not recommended to establish the histopathologic diagnosis of toxocariasis.

The diagnosis is most often established by confirmatory serologic testing using an enzyme-linked immunosorbent assay (ELISA). Excretory-secretory (E-S) proteins from second-stage *T. canis* larvae maintained in vitro form the substrate for the ELISA.<sup>77</sup> The sensitivity has been estimated to be approximately 78%, with a specificity of approximately 92% at a cutoff dilution value of 1:32.<sup>78,79</sup> Limited data indicate no significant cross-reactivity in individuals infected with common helminth infections.<sup>34,80</sup> An ELISA based on IgE-subclass antibodies appears to be comparably sensitive for detection and post-treatment follow-up of human toxocariasis.<sup>81</sup> A Western blot using toxocaral E-S antigens is more specific,<sup>82</sup> but is more labor-intensive. More recently, an immunoblot assay has been developed using a recombinant E-S antigen.<sup>83</sup> Unfortunately, none of these serologic tests can distinguish between past and current infection. An antigen capture test using a monoclonal antibody to toxocaral excretory-secretory antigen offers the ability to distinguish current infection. Preliminary data indicate the test is more than 50% sensitive; however, there is a false positive rate of 25% in patients with filariasis and schistosomiasis.<sup>84</sup>

The diagnosis of OLM is based on typical clinical findings of a retinal or peripheral granuloma or endophthalmitis, plus an elevated antibody titer to *T. canis* larval antigens. Identification of characteristic CT or ultrasonographic findings can facilitate diagnosis.<sup>85,86</sup> Although the finding of elevated *Toxocara* antibodies helps to establish the diagnosis of OLM, patients can sometimes have low or even negative titers.<sup>87,88</sup> Finding elevated *Toxocara* antibodies in the vitreous and aqueous humor can also facilitate the diagnosis.<sup>89,90</sup> Other nematode infections of the eye (e.g., cysticercosis, onchocerciasis, and diffuse unilateral subacute neuroretinitis) have to be carefully considered in the differential diagnosis.<sup>91</sup>

Covert toxocariasis should be considered in individuals of any age who present with chronic weakness, abdominal pain, or allergic signs accompanied by elevated IgE levels and eosinophilia. Finding antitoxocaral antibodies in serum does not necessarily establish the diagnosis but, in the absence of response to skin or pulmonary allergens, would certainly support it.

## TREATMENT AND PROGNOSIS

The majority of patients with toxocariasis do not require treatment, since the disease is usually self-limited; nevertheless, the disease can be fatal in severe cases. Treatment is generally reserved for patients with severe disease, although this remains a controversial point.

Acute VLM in children and adults is usually treated either symptomatically or with specific antihelminthic therapy, depending on the severity of clinical disease. Patients with either mild visceral larva migrans or covert toxocariasis and peripheral eosinophilia are often treated conservatively, since these forms of the disease are usually self-limited. Asymptomatic subjects with eosinophilia and those with covert toxocariasis in the absence of eosinophilia do not normally require any specific therapy.

Generalized treatment recommendations are limited by a paucity of controlled clinical data. Thiabendazole, mebendazole, diethylcarbamazine (DEC), albendazole, and ivermectin have been examined as treatments for VLM. Thiabendazole appears to be ineffective in asymptomatic children with toxocariasis, as measured by serial eosinophil counts and antitoxocaral antibody titers.<sup>68</sup> In patients with clinical illness, thiabendazole (15 mg/kg/day) appeared to be effective; however, a similar course of albendazole resulted in more frequent clinical cure and a measurable decrease in eosinophil counts.<sup>92</sup> A dose of 400 mg of albendazole twice a day for 5 days is the currently recommended therapy.<sup>93</sup> Alternatively, a 21-day course of mebendazole (20–25 mg/kg/d) has also been shown to be effective.<sup>94</sup> For those with severe symptoms treated with either albendazole or mebendazole, corticosteroids are often administered concomitantly (prednisone 0.5–1.0 mg/kg/d). Several small studies have demonstrated that a 21-day course of DEC (~6 mg/kg/d) results in resolution of clinical symptoms and a decline in antitoxocaral antibody titers, although patients experienced a significantly higher rate of adverse reactions.<sup>94</sup> In the United States, DEC is only available through the Centers for Disease Control and Prevention (CDC) Drug Service.

Albendazole has been found to be effective in OLM, but higher doses (adults, 800 mg bid; children, 400 mg bid) have been used in these clinical studies.<sup>95</sup> Albendazole should be administered for 4 weeks, with concomitant glucocorticoids (prednisone 0.5–1.0 mg/kg/d) for 2 to 4 weeks. Despite the promise of medical therapy, surgery is still sometimes required to treat OLM.<sup>96</sup>

## PREVENTION AND CONTROL

An association with dogs has been identified as a substantial risk factor for the development of toxocariasis.<sup>20,97</sup> While the prevalence of dog ownership varies throughout the world, most of the world's population shares its environment with *T. canis*-infected dogs. Thus, exposure to canine ascarids is likely to be widespread. In the United States, an estimated 53 million dogs are distributed among 31 million households.<sup>98</sup> This number is not expected to decline for the foreseeable future.<sup>99</sup> While the true incidence of toxocariasis is unknown in the United States, one would assume a significant portion of these animals are infected given the cosmopolitan distribution of the parasite.

While discouraging geophagia in children is a laudable goal, such behavior modification in this age group is essentially unrealistic. Instead, measures that prevent infected dog feces from contaminating the environment are of paramount importance. These measures include keeping dogs on a leash and excluding pet animals from playgrounds and sandboxes where geophagia occurs. Placing a vinyl covering over sandboxes at night has been shown to reduce the viability of *T. canis* eggs.<sup>100</sup>

An education campaign to highlight the risk to humans would be a logical component of any control program.

An effective surveillance and control program would require attention to potentially infected animals. However, pups and kittens are frequently not brought to veterinarians until they are at least 6 weeks old, by which time exposure to environments with extensive contamination with *Toxocara* eggs may have already occurred. Despite this obstacle, the prevalence of canine infection with *T. canis* has declined as a result of animal control measures and the widespread veterinary use of broad-spectrum anthelmintics effective against the adult worms.<sup>101</sup> Using subcutaneous ivermectin,<sup>102</sup> topical selamectin (a macrocyclic lactone similar to ivermectin),<sup>103</sup> or oral fenbendazole<sup>104</sup> at scheduled intervals during pregnancy dramatically reduced the worm burden carried by puppies. As of this writing, there is no available vaccine; however, potential candidates have been identified.<sup>105</sup>

### Cutaneous Larva Migrans

Cutaneous larva migrans (CLM), also known as creeping eruption, is a zoonosis caused by animal hookworms, most often that of the dog (*Ancylostoma caninum*) or cat (*Ancylostoma braziliense*).

Infected animals shed eggs in the stool that subsequently hatch, yielding first-stage larvae that mature into infective third-stage larvae in the soil. As with human hookworms, the infection starts when the worm enters the skin from contaminated soil that is protected from desiccation and temperature extremes, such as on beaches and under houses. As in toxocariasis, the worm cannot complete the infective cycle, so it continues to burrow through the subcutaneous tissues, resulting in the characteristic serpiginous, erythematous, elevated, and pruritic skin lesion (Fig. 103-3). The pruritus is sometimes incapacitating. The infection is often seen in travelers who have walked barefoot on beaches frequented by roaming cats and dogs. CLM is the most common dermatologic problem to affect Westerners after travel to tropical countries.<sup>106</sup> Almost one-third of travelers had symptoms for more than 4 weeks before the diagnosis was properly established.<sup>107</sup> In European travelers, the lesions are very few in number and most commonly involve the feet and buttocks. In contrast, a recent

**FIGURE 103-3** Typical lesion of cutaneous larva migrans involving the foot.

study of CLM in an endemic area indicates the clinical presentation is different from that reported in travelers.<sup>108</sup> Lesions were more frequent and spared the feet, most often occurring on the trunk, legs, and arms.

Systemic symptoms and eosinophilia are rare. The diagnosis is made solely on clinical grounds; skin biopsy is of negligible value. Other diagnoses to be considered include larva currens due to *Strongyloides stercoralis*, jellyfish stings, phytophotodermatitis, and myiasis. As with many other tropical diseases presenting in industrialized nations, physicians' lack of familiarity with this entity results in a significant delay in diagnosis and effective treatment. Even without treatment the lesions resolve spontaneously in 2 to 8 weeks, although longer periods of infection have been occasionally reported,<sup>109</sup> and the patients are often miserable due to pruritus.

Albendazole is well tolerated and quite effective, resolving the infection within 1 week<sup>110</sup>; however, clinical trials have yielded conflicting results with respect to the optimal dosage. It would appear that travelers with CLM should be treated with 400 to 800 mg/d for 3 to 5 days.<sup>111</sup> A single dose of ivermectin (200 µg/kg on an empty stomach) is well tolerated and curative in 77% of patients; 97% were cured with one or two supplemental doses, if necessary.<sup>112</sup> The median time required for pruritus and lesions to disappear was 3 and 7 days, respectively.

Topical cryotherapy is not recommended because it does not work and is potentially harmful to the patient.<sup>111</sup> Topical application of a 10% to 15% thiabendazole solution/ointment to the affected area effects a cure within 10 days in 98% of patients. Thiabendazole is also effective against CLM when given orally, although less so; 89% of patients are cured after 4 weekly doses. The side effects of oral thiabendazole make topical treatment attractive; however, this treatment has limited value for multiple lesions. Topical thiabendazole preparations are not commercially available in the United States.

# Trichinellosis

FABRIZIO BRUSCHI  
K. DARWIN MURRELL

## INTRODUCTION

Trichinellosis, the proper term for trichinosis or trichiniasis, results from infection by a parasitic nematode belonging to the genus *Trichinella*. Trichinellosis has been an important, though often unrecognized, disease for thousands of years. Species of *Trichinella* responsible for the infection are widely distributed, including the Arctic, temperate lands, and the tropics.<sup>1</sup> Virtually all mammals are susceptible to infection; however, humans appear to be especially prone to developing clinical disease. Infection with various species of *Trichinella* is far more common than is generally recognized. Although the incidence of human trichinellosis is low worldwide, the parasite remains an important food-borne zoonosis because of its epizootic nature and the economic burden associated with preventing its incursion into the human food chain.<sup>2</sup> The prevalence of swine trichinellosis and the incidence of human trichinellosis appear to be greater in developing countries, such as China, Thailand, Mexico, Argentina, and Bolivia, and in some central European countries.<sup>3</sup>

Until recently, the epidemiology and systematics of this parasitic zoonosis were considered relatively simple and straightforward.<sup>1</sup> Human trichinellosis was believed to involve one species, *Trichinella spiralis* (Owen, 1835). During the past two decades, major changes in the understanding of this epidemiology have occurred, yielding a transmission pattern that may involve domestic swine, horses, and wild animals. Furthermore, new molecular genetic data have led to the creation of a new taxonomy for *Trichinella* that includes eight species rather than one<sup>1</sup> (Table 104-1). This revised taxonomy is yielding a greater comprehension of the clinical course of the disease caused by the different *Trichinella* species.<sup>4</sup> Although this parasite was first described more than 155 years ago, both its biology and its complete control remain an unfinished story.

## AGENT

The parasite's discovery resulted from the microscopic examination of cadaver muscle in London in 1835, and it was named *Trichina spiralis* by Owen. During the mid-19th century, the life cycle and etiology of human-swine trichinellosis were elucidated by German scientists, along with its basic epidemiology. Over the succeeding 150 years, the domestic pork-human trichinellosis cycle was reported from many countries. In some regions, especially in Europe and the former Soviet Union, the problem of trichinellosis was so severe that mandatory inspection of all pork for muscle larvae

(trichinae) was instituted. These measures have been effective and in countries with mandatory meat inspection, trichinellosis has become a low-incidence disease.

The classic and most frequent cause of human trichinellosis, *T. spiralis*, is normally derived from domestic pork; the pig-man epidemiologic pattern is usually referred to as the synanthropic or domestic cycle. All species of *Trichinella* are morphologically difficult to distinguish from one another, but all have a direct life cycle with complete development in a single host; there is a degree of host specificity, but the complete host range for each species is not completely known. The host capsule surrounding the infective larvae is a modified striated muscle structure called a nurse cell, which is digested away in the stomach when the infected muscle is ingested by the next host.<sup>5</sup> The free larvae (L1 stage) then move into the upper small intestine and invade the columnar epithelial intestinal cells. Within 30 hours, the larvae undergo four molts to reach the mature adult stages, as males and females. After mating, the female (Fig. 104-1) begins shedding live newborn larvae (NBL), approximately 5 days postinfection; the NBL are early developmental forms of the L1 stage.<sup>3</sup> The persistence of adult worms in the intestine of humans may last for several weeks.<sup>4,5</sup> The NBL migrate throughout the body via the blood and lymph circulatory system. Although the NBL may attempt to invade many different tissues, they are successful only if they can enter striated skeletal muscle cells.<sup>6,7</sup> The NBL continue to grow and develop during the first 2 weeks of intracellular life until they reach the fully developed L1 infective stage. The longevity of the nurse cell-L1 complex (encapsulated) appears to vary by parasite and host species, but it generally persists for 1 to several years before calcification and death occur.<sup>8</sup> The life cycle is completed when the host's infected muscle is ingested by a suitable host. A host capsule does not develop around *T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis* muscle larvae.<sup>8</sup>

## EPIDEMIOLOGY

The most salient feature of this parasite group's epidemiology is its obligatory transmission by ingestion of meat. A second cardinal feature is its existence in two normally

**Table 104-1** Biologic and Zoogeographic Features of *Trichinella* Species

Species	Distribution	Major Hosts	Reported from Humans
<i>T. spiralis</i>	Cosmopolitan	Domestic pigs, wild mammals	Yes
<i>T. britovi</i>	Eurasia	Wild mammals	Yes
<i>T. murrelli</i>	North America	Wild mammals	Yes
<i>T. nativa</i>	Arctic	Bears, foxes	Yes
<i>T. nelsoni</i>	Equatorial Africa	Hyanas, felids	Yes
<i>T. pseudospiralis</i> *	Cosmopolitan	Wild mammals, birds	Yes
<i>T. papuae</i> *	Papua New Guinea	Domestic/feral pigs	No
<i>T. zimbabwensis</i> *	Tanzania	Crocodiles	No

\*Nonencapsulating species.

**FIGURE 104-1** Living female adult worm of *Trichinella britovi*, isolated from the intestine of a rat at 6 days of infection. At this magnification it is possible to observe the embryos in the uterus cavity. (Phase contrast; original magnification  $\times 1000$ .)

separate ecological systems, the sylvatic and the domestic. In certain circumstances, the two biotopes are linked through man's activities, resulting in the exposure of humans to *Trichinella* species normally confined to sylvatic animals. The species most frequently associated with human infection is *T. spiralis*, the species that is normally found in domestic pigs but frequently detected in rodents and wild mammals.<sup>4</sup> The domestic cycle of *T. spiralis* involves a complex set of potential routes.<sup>4</sup> Transmission on a farm may result from predation on or scavenging other animals (e.g., rodents), hog cannibalism, and the feeding of uncooked meat scraps. The importance of wild animal reservoirs is often underappreciated, although the frequency of transmission from infected game animals is significant.<sup>8</sup>

The worldwide incidence of human trichinellosis has declined substantially during the past few decades, but outbreaks are still frequent, especially in developing regions<sup>3</sup> (Table 104-2). In developed countries, the epidemiology of human trichinellosis is typified by urban common-source outbreaks.<sup>4</sup> In the United States, the largest human outbreaks

**Table 104-2** Examples of Recent Human Trichinellosis Cases in Different Countries

Country	Period	No. of Cases	Sources
United States	1991–1996	230	Pork, game
Mexico	1991–1998	280	Pork
Argentina	1990–1999	5,217	Pork, game
Bulgaria	1993–2000	5,683	Pork, game
Croatia	1997–2000	1,047	Pork
Serbia	1995–2001	3,925	Pork
Romania	1990–1999	16,712	Pork
France	1995–1997	27	Game, horse
Italy	1999–2001	164	Pork, horse, game
Spain	1993–1998	290	Pork, game
China	1964–1999	23,004	Pork, dogs, game, mutton
Thailand	1994–1996	104	Pork, game

have occurred among ethnic groups with preferences for raw or only partially cooked pork. Infected meat is typically purchased from local supermarkets, butcher shops, or other commercial outlets. However, in recent years, nearly one-third or more of human infections in the United States have been derived from wild animal meat.<sup>3,4</sup> In Europe, where the safeguard of pork inspection is mandatory, most recent outbreaks have resulted from infected horse or wild boar meat.<sup>2,9</sup> The resurgence of trichinellosis in central Europe appears to result from increased transmission from both pork and wild game. In Latin America<sup>10</sup> and Asia, however, domestic pork appears to be the main source of infection.

Surprisingly, during the past 20 years, Europe has experienced six large outbreaks due to infected horse meat, a heretofore unrecognized source of infection.<sup>4,8,9</sup> Three outbreaks occurred in France in 1976 (125 patients) and two in 1985 (400 and 980 patients). Three outbreaks occurred in Italy—one in 1976 (96 patients), one in 1984 (13 patients), and one in 1986 (300 patients). Four of the outbreaks were shown to be due to *T. britovi*, one to *T. nativa*, and one to *T. spiralis*.<sup>9</sup>

Foreign travelers also account for some cases of human trichinellosis; 26 cases occurred from 1975 to 1989 in the United States, most of them after travel to Mexico or Asia. Globally, the prevalence of *T. spiralis* in domestic swine ranges from less than 0.001% (United States) to 25% or more (e.g., some regions of China). The global rise in consumer demand for greater food quality assurance also makes eradication of *T. spiralis* from pork an unavoidable responsibility of both producers and governments.

## DISEASE

The clinical course of the acute period of infection is characterized by two phases: *enteral* (the parasite alters intestinal function) and *parenteral*, associated with an inflammatory and allergic response to muscle invasion by the larval parasites.<sup>11</sup> Gastrointestinal signs appear first, a result of mucosal invasion by the first-generation (ingested) larvae. These signs typically last 2 to 7 days but may persist for weeks. Subsequently, fever, myalgia, periorbital edema, and eosinophilia, which together constitute the so-called trichinellotic syndrome or general trichinellosis syndrome, begin.<sup>12,13</sup> However, the acute

phase, lasting 1 to 8 weeks, is commonly asymptomatic, especially when the number of ingested larvae is low.

The severity of the clinical course depends on the parasite and host factors,<sup>12</sup> such as immune status; this is particularly evident in patients treated with immunosuppressive drugs for kidney transplantation.<sup>14</sup> In experimental infections, steroids and immunosuppressive treatments delay the worm expulsion,<sup>15</sup> and this probably also occurs in humans.<sup>11</sup> Furthermore, the prolonged diarrhea in the absence of myalgia, reported in elderly Inuit people, may be due to previously acquired immunity against the enteral and parenteral stages of the parasite.<sup>16,17</sup> The incubation period ranges from 7 to 30 days, depending on the severity of infection. When the course of infection is severe, the incubation period is brief, although death may also occur with a longer incubation period.<sup>12</sup>

The clinical course may be abortive (symptomatology not complete), mild (complete even if mild), moderate, or severe (often with complications).<sup>13</sup> Malaise, anorexia, nausea, vomiting, abdominal pain, fever, diarrhea, or constipation may occur. Diarrhea is more persistent than vomiting, lasting up to 3 months, and, when excessive, causes dehydration; this, together with enteritis, is an occasional cause of death. Variations in this pattern occur. For example, in outbreaks in the Canadian Arctic caused by the Arctic species *T. nativa*, trichinellosis occurred in two forms: the classic myopathic form and a clinical syndrome featuring prolonged diarrhea without fever and only a brief period of myalgia, affecting primarily elderly patients.<sup>16,17</sup>

Muscles are mainly affected during the parenteral phase, but other organs, such as the myocardium, central nervous system (CNS), lungs, kidney, and skin, may also be involved. The trichinellotic syndrome is characterized by facial edema; muscle pain and swelling; weakness; and, frequently, fever; anorexia, headache, conjunctivitis, and urticaria occur less frequently. Fever, usually remittent, generally begins at 2 weeks and peaks after 4, with temperatures as high as 40 or 41°C in severe cases. Despite fever, patients may appear in good condition. Ocular signs at this time may help in diagnosis, in particular edema of the eyelids, chemosis, conjunctivitis, conjunctival hemorrhages, disturbed vision, and ocular pain. Periorbital edema is peculiar to trichinellosis, ranging from 17% to 100% in more than 2100 trichinellosis cases reviewed.<sup>18</sup> The mechanisms responsible for this edema are not clear, but an allergic phenomenon is probably responsible.<sup>18</sup>

The entire face may also be involved, giving patients a characteristic aspect, often rendering them unrecognizable. At this time, the muscles of the rest of the body usually become painful. Extraocular muscles, masseters, tongue and larynx muscles, diaphragm, neck muscles, and intercostal muscles are most frequently infected. The pain may be so severe as to limit function of the arms and legs, inhibiting walking, speaking, moving the tongue, breathing, and swallowing. Weakness is also a consequence of the muscle involvement. The muscles become stiff, hard, and edematous; the edema may be so intense as to simulate hypertrophy.<sup>19</sup> Edema lasts 1 or 2 weeks and disappears with increased diuresis. In an outbreak in Thailand due to *T. pseudospiralis* myalgia and asthenia lasted more than 4 months.<sup>20</sup>

Gastrointestinal symptoms, such as vomiting and diarrhea, may also extend into this phase.<sup>12</sup> Dyspnea (even ventilatory failure),<sup>21</sup> coughing, and hoarseness may also be present. Dyspnea is caused primarily by parasite invasion and consequent

inflammation of respiratory muscles such as the diaphragm (the most heavily infected muscle in experimental animal infections<sup>22</sup>). Bronchopneumonia and infarction may also be responsible. The cough begins in correspondence with the passage of the larvae through the capillary bed of the lungs approximately 1 week after infection.<sup>23</sup>

Neurologic manifestations, more common in severe infections, occur in 10% to 24% of cases.<sup>24,25</sup> In 55 patients affected by neurotrichinosis (involvement of the CNS), meningoencephalitic signs were observed in almost all cases. Less frequent signs are focal paralysis or paresis, delirium, and psychosis.<sup>25</sup> Headache is very common in trichinellosis, being exacerbated by movements of the head. Myocarditis is the most frequent cardiovascular complication. It is sometimes responsible for heart failure or bronchopneumonia; in some cases, death occurs between the fourth and the eighth week of infection, although sudden death may occur even earlier.<sup>12</sup> Arrhythmias, secondary to myocarditis, may also occur. In one case, it was necessary to use a pacemaker for 1 year to maintain normal cardiac rhythm.<sup>21</sup> Electrocardiographic alterations (premature contractions, prolongation of the P-R interval, small QRS complexes with intraventricular block, and flattening or inversion of the T waves, especially lead II and precordial leads) may be present from the second week and may persist up to the third or fourth week. Blood pressure may be low during the early phase of infection and also during convalescence. Edema due to heart failure has been observed, generally in the later phase of the infection when edema due to myositis has almost disappeared. Vascular signs such as epistaxis, hemoptysis, hemorrhages from the bowel, thrombosis of the femoral or pulmonary artery, and embolism are less common. In one fatal case, the arterioles of different organs were affected by disseminated intravascular coagulation with platelet-fibrin thrombi.<sup>26</sup> Less frequent are petechial hemorrhages, mainly subungual resembling bacterial endocarditis, and roseola and maculopapular exanthems, resembling measles.<sup>23</sup> After the acute period, convalescence follows (lasting from months to years), usually with a complete recovery. During the first few years, muscle larvae are slowly but completely destroyed, followed by calcification.<sup>27</sup> Although this is true for *T. spiralis* infections, the calcification process in infections with other species may occur earlier.<sup>28</sup>

The existence of chronic trichinellosis<sup>29</sup> or “persisting sequelae”<sup>30</sup> (the persistence of myalgia, early fatigability, ocular signs, and headache for decades) is somewhat controversial and requires investigation. Some studies have confirmed the occurrence of these sequelae for periods up to 10 years after clinical recovery.<sup>31,32</sup>

Although death is now rare in trichinellosis, owing to improved therapy, it may result from congestive heart failure due to myocarditis, encephalitis, pneumonitis, hypokalemia, or adrenal gland insufficiency.<sup>12,23</sup> In the United States, during the period 1991 to 1996, in 230 cases of trichinellosis reported to the Centers for Disease Control and Prevention, only 3 were fatal.<sup>33</sup> During an outbreak in Thailand caused by *T. pseudospiralis*, one fatality was reported in 59 patients and it was attributed to the high number of larvae ingested rather than to pathogenicity of the *Trichinella* species involved.<sup>20</sup>

## **PATHOGENESIS AND IMMUNITY**

The early phase of infection, associated with the presence of the parasite in the gastrointestinal tract, induces a type 1

hypersensitivity reaction, a result of Th2 cell activation, leading to increased levels of parasite-specific IgE and eosinophils. A clear role for IgE in protective intestinal immunity has been documented in rodent models that show that parasite-specific IgE, transfused together with thoracic duct cells from immune animals, induces rapid intestinal worm expulsion during a primary infection.<sup>34</sup> However, the mechanisms regulating the response to a primary infection, especially in human hosts, are not clear. The prolonged diarrhea observed in the outbreaks in the Canadian Arctic<sup>16,17</sup> suggests adult worms persist in the intestine of people with frequent exposure to infection, a circumstance that arises from possible downregulation of the intestinal immune response, a premunition state, or a downregulation of gut physiology.

Recently, it has been shown in infected mast cell-depleted animals as well as in interleukin-9 (IL-9) transgenic mice (mast cell overproduced) that mast cells are responsible for the modifications of the intestinal epithelial barrier, including production of a mucosal chymase, occurring during *T. spiralis* infection, which lead to an increased mucosal leakiness.<sup>35</sup> The effect of this protease, increasing gut permeability, could facilitate the passage of antibodies to the lumen.

The parenteral phase is associated with inflammatory and allergic responses to invasion of the muscles by the migrating larvae. This invasion can directly damage the muscle cells or indirectly stimulate the infiltration of inflammatory cells, primarily eosinophils. These cells may damage the muscle tissue.<sup>36</sup> Neurotrichinosis arises mainly from vascular perturbations, such as vasculitis and granulomatous inflammatory reactions that surround invading larvae. The larvae tend to wander, causing damage before reentering the bloodstream, or they remain trapped and are destroyed by the provoked granulomatous reaction.<sup>37</sup> Neural cells may also be damaged by eosinophil degranulation products such as eosinophil-derived neurotoxin and major basic protein (MBP).<sup>38,39</sup> Myocarditis results initially from invasion by the migrating larvae, followed by immunopathologic processes such as eosinophil infiltration and mast cell degranulation, according to results obtained in experimental infection.<sup>40</sup>

The mechanisms responsible for the pronounced eosinophilia, so characteristic of trichinellosis, are not well understood. The involvement of factors specific for eosinophils such as cytokines, including IL-5<sup>41,42</sup> produced by the Th2 subset of CD4<sup>+</sup> T cells,<sup>43</sup> may be involved. The role of IgE in inducing the eosinophilia is controversial.<sup>44,45</sup> Eosinophils are cytotoxic for newborn larvae in vitro in both animal<sup>46,47</sup> and human antibody-dependent cellular cytotoxicity in vitro reactions<sup>48,49</sup>; they release products such as MBP,<sup>50</sup> peroxidase,<sup>51</sup> or products derived from oxidative metabolism.<sup>52</sup> However, their actual role in vivo is not understood. Interestingly, suppression of eosinophilia by an IL-5-specific monoclonal antibody in vivo does not modify either primary or secondary *Trichinella* infections in mice.<sup>53</sup>

## **DIAGNOSIS**

The issue of whether trichinellosis is a low-prevalence disease or one that is frequently misdiagnosed cannot be adequately resolved. Diagnosis is difficult in low-level, sporadic infections because the resulting clinical manifestations are common to many other diseases,<sup>23</sup> including chronic fatigue syndrome.<sup>54</sup> Trichinellosis should be considered in the

differential diagnosis of myositis in patients with human immunodeficiency virus (HIV) infection.<sup>55</sup> When the infection occurs in epizootic or outbreak form its diagnosis is easier. Special care must be taken when developing clinical histories, giving particular attention to eating habits during the weeks before the onset of symptoms. Ingestion of infected meat (raw or undercooked); the presence of gastroenteritis, myalgia, facial edema, subungual or conjunctival hemorrhages; and an increase in eosinophils should suggest trichinellosis.<sup>12</sup> Electromyography (EMG) may help in the diagnosis of moderate and severe infections during the acute period, even if the muscle changes are not pathognomonic.<sup>12</sup> With clinical improvement, EMG changes generally disappear within 2 or 3 months<sup>56</sup> but may persist for 1 to 8 years,<sup>57</sup> or more.<sup>58</sup>

A definitive diagnosis may be made when L1 stage larvae are found in a muscle biopsy, generally performed in the more accessible deltoid muscle. Biopsy is recommended only in rare and difficult cases, particularly when serology is not clear. If the result is negative, however, a low-level infection cannot be excluded.<sup>12</sup> Artificial digestion (1% pepsin-HCl) of a muscle sample is more sensitive than direct microscopic observation of the tissue specimen, but, importantly, larvae cannot be isolated from muscle before 17 to 21 days of infection because of their sensitivity to digestion.<sup>59</sup> A muscle biopsy may help, however, not only in diagnosis but also in evaluating the level of infection, the pathologic changes in the muscle tissue, and the infection duration and in the isolation of the parasite and its subsequent genetic typing by molecular techniques<sup>60</sup>; this is important when the source of infection is unknown or no longer available. This technique allowed for the first time the identification of *T. pseudospiralis* in a human trichinellosis case.<sup>61</sup> All such information is useful in deciding on therapeutic strategies.<sup>12</sup>

The histologic examination may reveal modifications of skeletal muscles, including at first a basophilic degeneration of the fibers, fatty metamorphosis, hyaline or hydropical degeneration or both, and interstitial inflammation; sometimes it is possible to observe dead nonencapsulated parasites. Small hemorrhages, the accumulation of inflammatory cells (myositis) such as eosinophils, lymphocytes, and macrophages, among the muscle cells are also visible. Inflammatory cells invade the muscle cells when the sarcolemma is damaged. Vascularity increases near muscle fibers.<sup>62,63</sup> The process of encapsulation of the parasite, with the exception of *T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis*, begins at approximately 2 weeks and is usually completed at 5 weeks of infection, depending on the *Trichinella* species involved.<sup>28</sup> In humans, calcification begins approximately 5 months after infection and is usually completed after 18 months.

As previously mentioned, the diagnosis of trichinellosis is difficult in sporadic cases, but it is even more difficult when CNS involvement is present. Neurotrichinosis is sometimes accompanied by multifocal CNS lesions, nodular or ringlike, with a diameter of 3 to 8 mm, and, in most cases, showing contrast enhancement.<sup>39,64</sup> However, in cases with neurologic manifestations of trichinosis, computed tomography images of the brain have been reported to be normal.<sup>64,65</sup>

Eosinophilia, leukocytosis, serum muscle enzyme-level increases, and increased immunoglobulin levels, especially total IgE, are the most characteristic laboratory findings in this disease. Eosinophil levels increase dramatically during trichinellosis (up to 8700/ $\mu$ L).<sup>11</sup> Eosinophilia (based on the absolute number rather than the percentage) occurs in all cases

of trichinellosis, even the subclinical; the exception may be very severe infection with eosinopenia, which has a fatal course.<sup>66</sup> Eosinophilia may also be absent when bacterial infections complicate the disease. After steroid therapy, eosinophil levels also decrease.<sup>12</sup> Leukocytosis, up to 24,000/ $\mu$ L,<sup>67</sup> occurs in very severe infections, usually early in the infection.

Increased creatine phosphokinase (CPK), lactate dehydrogenase (LDH), aldolase, and aminotransferase levels reflect skeletal muscle damage, helping in the diagnosis.<sup>12</sup> Serum CPK levels can increase up to more than 17,000 U/L. CPK isoenzyme profiles, however, are not very helpful. An increased level of the CPK isoenzyme MB, generally ascribed to myocardial damage, has been observed in 35% of trichinellosis patients examined with no cardiologic symptoms, suggesting a release of this isoenzyme from damaged skeletal muscle cells.<sup>68</sup> LDH should be evaluated together with CPK, even if the former is less specific. When high levels of CPK and LDH are present, a differential diagnosis with myopathies is necessary. Before antibody levels increase, the level of total serum LDH and of the isoenzymatic forms LD<sub>4</sub> and LD<sub>5</sub> may increase in approximately 50% of patients.<sup>69</sup>

Hypoalbuminemia is observed mainly in severe cases, in which the amounts of this serum protein can reach 2.5 g/dL.<sup>13</sup>

Immunoglobulin level changes may also occur, the most characteristic being an increase in total IgE. However, an increase in total IgE levels is not a consistent phenomenon, and it is not possible to exclude trichinellosis by its absence.<sup>12</sup> A poor correlation with specific IgE has been observed for both *T. spiralis*<sup>70</sup> and *T. britovi*.<sup>71</sup> infections.

Many serologic tests are available for diagnosis.<sup>12,59</sup> There are three objectives in immunodiagnosis: (1) recognizing the acute infection to allow early anthelmintic treatment, (2) making a retrospective diagnosis, and (3) adding information to the epidemiology of the infection.<sup>72</sup>

Seroconversion usually occurs between the third and fifth week of infection and serum may remain positive up to 1 year or more after cessation of clinical symptoms. Antibodies have been detected, however, up to 19 years after the end of the acute phase of infection.<sup>12</sup> Antibody levels do not correlate with the severity of the clinical course<sup>69</sup> or with a particular clinical course.<sup>73</sup>

Indirect hemagglutination, bentonite flocculation, indirect immunofluorescence (IFA), latex agglutination, and enzyme-linked immunosorbent assay (ELISA) are the more commonly used tests, the last of which is the most sensitive.<sup>12</sup> Factors such as sensitivity, specificity, convenience, simplicity, cost, and commercial availability must be considered when choosing a test. However, a diagnostic laboratory should have at least two or more tests available to ensure a correct diagnosis: one to detect the response against a soluble antigen and another for antibodies that react with parasite surface antigens.<sup>72</sup> For the latter, the IFA is performed with whole L1 stage larvae killed with formalin<sup>74</sup> or with unfixed frozen sections of infected muscles<sup>75</sup>; the latter is more sensitive. With this test, all specific immunoglobulins can be evaluated. The ELISA method,<sup>76</sup> using excretory-secretory antigens, is preferable to that which uses crude extracts of *T. spiralis* muscle larvae for soluble antigen because it is more specific. This is particularly important in tropical regions where cross-reactions with other helminth parasites can give false-positive results.<sup>77,78</sup> Cross-reactions with *Trichinella* antigens were observed in patients with autoimmune diseases.<sup>79</sup> It is necessary to standardize as much as possible the antigens used for

diagnostic purposes.<sup>80,81</sup> Recombinant<sup>82</sup> or synthetic<sup>83</sup> antigens are now available for diagnostic purposes. The ELISA can also be used for the evaluation of the different specific Ig classes (IgA and IgM)<sup>84,85</sup> or IgG subclasses,<sup>86</sup> but the sensitivity of these tests is lower than that of the ELISA IgG. The data on specific IgE are contradictory,<sup>77,84,85</sup> however, and this test cannot yet be recommended. The detection of circulating antigens has also not been completely satisfactory compared to IFA or a competitive inhibition assay.<sup>87</sup> However, it is worthwhile because it may demonstrate early the actual presence of the parasite and may represent an alternative to muscle biopsy.

The study of the cellular immune response in humans<sup>88</sup> is important for research purposes but of little value for diagnosis. Immunoelectrotransfer blot assay<sup>89,90</sup> can be used as a primary or confirmatory test. When ES antigens are used, it is quite specific and useful for follow-up studies.<sup>61</sup> In accordance with the International Commission on Trichinellosis, the serum reactivity for the TSL-1 antigen family (40 to 70 kDa in the reduced form) should be considered diagnostic.<sup>81</sup>

## TREATMENT AND PROGNOSIS

It is difficult to differentiate the efficacy of drug therapy from natural recovery of infection in mild to moderate cases. Factors such as the *Trichinella* species involved, intensity and length of infection, and host response can aid in deciding on the treatment course.<sup>12</sup> Symptomatic treatment<sup>66</sup> includes analgesic and antipyretic drugs, bed rest, and corticosteroids (prednisolone at 50 mg/day), especially in severe infections to prevent shocklike symptoms. Specific treatment<sup>66</sup> is performed with mebendazole, which should be administered in adults at a daily dose of 5 mg/kg in two doses for 10 to 15 days (the treatment cycle may be repeated after 5 days) or with albendazole. In adults, this latter drug should be administered at a dose of 15 mg/kg/day in two doses for 10 to 15 days; in children older than 2 years, the drug is given at 10 mg/kg/day. For severe infection, the treatment may be repeated after 5 days. Blood cell counts and liver function should be regularly monitored. Albendazole in pregnant women is contraindicated and in children younger than 2 years is not recommended. Thiabendazole is no longer used because of its side effects.<sup>66</sup> Pyrantel has been proposed for children and pregnant women, but its efficacy is doubtful.<sup>56</sup> This treatment is recommended for intestinal and muscle stages, but light infections do not require treatment. The treatment goal for the very early infection phase is to limit muscle invasion by larvae; when this has already occurred, the goal is to reduce muscle damage, which is responsible for the major clinical manifestations. Therapeutic plasma levels of the drug should be maintained for an extended period rather than high levels for short periods. The success of treatment is evident from clinical improvement of the patient's symptomatology.

As previously mentioned, the prognosis *quoad vitam* is usually good with the exception of rare, heavily infected cases. That *quoad valetudinem* depends on the number of ingested larvae and on the time passed before the diagnosis has been made and treatment begins.

## PREVENTION AND CONTROL

Control of swine trichinellosis and prevention of infection in humans have both direct and indirect aspects. Mandatory

inspection of pork at slaughter, although common in developed countries, especially Europe,<sup>91</sup> is not required in the United States. In developing countries, testing for trichinellosis as part of routine inspection is rare. Instead, emphasis is placed on educating the consumer on safe handling and cooking of pork and wild game. The U.S. Department of Agriculture has established recommended procedures<sup>92</sup> for devitalizing any muscle larvae present in these meats by cooking or freezing. For example, the consumer should cook pork until all pink color has disappeared, which normally occurs at approximately 137°F; to allow for a margin of error, however, it is recommended that the internal temperature of meat should uniformly reach 160°F throughout, whether by conventional cooking or by microwaving. Care must be taken to avoid cold spots with the latter method.

Fresh pork less than 6 inches thick can be rendered safe if frozen to 5°F (−17°C) for 20 days, −10°F (−23°C) for 10 days, or −20°F (−29°C) for 6 days. Because of the freeze resistance shown by sylvatic species of *Trichinella*, particularly *T. nativa*, freezing of meat from game is not completely reliable. Infection from wild animal meat accounts for an important proportion of human trichinellosis; therefore, the inspection of wild game muscle is recommended and is mandatory in some European countries. Consumers should also be warned of the danger and advised on proper meat handling and preparation procedures.

The control of trichinellosis in swine relies on good general management practices.<sup>92</sup> For example, pork producers are encouraged to observe federal garbage feeding regulations in those states where this practice is allowed, to practice stringent rodent control, to avoid exposing pigs to dead animal carcasses of any kind, to ensure that hog carcasses are properly disposed of, and to try to establish effective barriers between domestic swine and wild and domestic animals.

A modest amount of research has been carried out on the development of a vaccine. Unlike rodents, the typical experimental host, pigs do not develop strong intestinal immunity<sup>93</sup>; hence, L1 stage stichocyte antigens are insufficient for a vaccine. However, the antigens of the NBL have proved highly effective in pigs, and a protovaccine has been developed.<sup>94</sup>

# Angiostrongyliasis

TIM KUBERSKI

## INTRODUCTION

Two species of *Angiostrongylus* cause two distinct diseases of importance. Their geographic distribution and clinical syndromes are different so they will be discussed separately. *Angiostrongylus cantonensis* causes a meningoencephalitis characterized by a high number of eosinophils in the cerebrospinal fluid (CSF). The disease is most commonly called eosinophilic meningitis and is prevalent in Southeast Asia and certain tropical Pacific islands. *Angiostrongylus costaricensis* causes an eosinophilic inflammation of the gastrointestinal tract that can mimic appendicitis and is found mainly in Central and South America.

## ■ *Angiostrongylus cantonensis*

### AGENT

*A. cantonensis* was first described from China in 1935.<sup>1</sup> It is also known as the rat lungworm, living as an adult in the pulmonary arteries of the rat. The life cycle involves rats and mollusks, with humans being incidental hosts. The first human infection was reported from Taiwan in 1945.<sup>2</sup> In rats, adult worms in the pulmonary arteries produce fertilized eggs that develop into first-stage larvae.<sup>3</sup> These larvae penetrate the lung arterioles and move into the respiratory tract. They are then coughed up, swallowed, and passed in the feces. The larvae remain viable in the feces for variable periods, depending on moisture. They can remain infectious for several weeks in freshwater.<sup>4</sup> The life cycle can be completed only if these larvae are consumed by an appropriate mollusk intermediate host, usually land snails or slugs.<sup>3</sup> The larvae then mature into infectious third-stage larvae that remain infectious for the life of the mollusk. When a rat consumes a mollusk with viable larvae, the larvae penetrate its intestinal wall and enter the bloodstream. It is neurotropic and migrates preferentially to the central nervous system (CNS). In the CNS of the rat, the larvae mature into the fifth stage (young adults) and make their way from the subarachnoid space and sinusoids of the CNS into the pulmonary arteries, completing the life cycle. If a human consumes a mollusk with viable larvae, the larvae migrate

## *Angiostrongylus cantonensis*\* (Rat Lungworm)

\* SE Asia, Pacific Is.  
also US ports, Cuba, Australia, Japan, China, Mauritius

to the CNS. However, because the human is an abnormal host, the parasite is unable to complete its life cycle and dies in the CNS.<sup>3,5</sup>

## EPIDEMIOLOGY

*A. cantonensis* is enzootic in Southeast Asia and on many tropical Pacific islands.<sup>6</sup> The first epidemic outbreaks of eosinophilic meningitis were reported from Ponape, Caroline Islands.<sup>7</sup> Many of the earliest reports of eosinophilic meningitis were from French Polynesia,<sup>8–10</sup> New Caledonia,<sup>9</sup> and Hawaii.<sup>9–11</sup> More recently, human cases have been described in Louisiana,<sup>12</sup> Australia,<sup>13</sup> Japan,<sup>14</sup> Vanuatu,<sup>15</sup> Fiji,<sup>16</sup> mainland China,<sup>17</sup> American Samoa,<sup>18</sup> Jamaica,<sup>19</sup> and in the Indian Ocean, Reunion and Mauritius.<sup>20</sup> Southeast Asia, Thailand,<sup>21</sup> and Taiwan<sup>22</sup> report the most cases. The parasite, and a few cases of human disease, have been reported from Africa.<sup>6</sup> Parasites without known human disease have been reported from Egypt, the Bahamas, and Puerto Rico.<sup>6</sup> The spread of this parasite is probably related to infected rats being transported to various places aboard ships or the introduction of mollusks such as the giant African snail (*Achatina fulica*), which is capable of carrying many parasites.<sup>6,22,23</sup>

Purposeful or inadvertent ingestion of uncooked or marinated snails is one of the most important pieces of historical information from patients. In Thailand, eosinophilic meningitis may be related to the ingestion of sliced, pickled *Pila* snails, which are eaten as a delicacy.<sup>21</sup> Outbreaks of eosinophilic meningitis have been associated with consumption of raw snails, *Achatina fulica*.<sup>24</sup> However, there are many sporadic cases in which there is no obvious exposure to mollusks. Since cases of eosinophilic meningitis have been reported in vegetarians,<sup>25</sup> it is postulated that larvae can remain viable in the slime of snails or slugs and cause infection when contaminated, unwashed vegetables are eaten.<sup>26</sup> Many cases in young children are attributed to the unobserved ingestion of a contaminated snail or slug.<sup>11</sup>

A cold-blooded predator or scavenger (paratenic host) can be an incidental carrier of larvae if it has ingested an infected mollusk.<sup>26</sup> Thus, freshwater shrimp or crabs could carry larvae capable of causing infection if eaten raw.<sup>27</sup> Infectious larvae have been shown to be viable for long periods of time in such hosts, many of which are eaten raw in many tropical cultures.<sup>26–28</sup> These larvae are not capable of completing their life cycle, but can remain viable for long periods of time. Water in wells or cisterns could also be a source of viable larvae, becoming contaminated when released from drowned terrestrial mollusks.<sup>9</sup> Contamination of fingers with larvae during the collection and preparation of snails for eating is another potential source of infection.<sup>22</sup>

## DISEASE

The incubation period is about two weeks.<sup>21</sup> Travel to an endemic area or exposure to mollusks is useful for establishing the time of exposure. The most common presentation is that of a nonbacterial meningitis.<sup>29</sup> Patients present with headache, nausea, vomiting, and neck stiffness.<sup>21,29,30</sup> Fever may not be a common finding in adults.<sup>11</sup> The main, and occasionally only, complaint is a headache, which is usually global and severe. The duration of illness ranges from 2 to 8 weeks.<sup>21,29,30</sup>

Paresthesias are a distinctive complaint; they are asymmetrical and usually noted on the extremities.<sup>21,29,30</sup> They are a complaint that may not be of obvious significance until the diagnosis of eosinophilic meningitis is considered. Paresthesias can separate this form of meningitis from others. The paresthesias can be persistent, lasting months after resolution of the illness.<sup>29,31</sup> Transient cranial nerve palsies, especially of the facial nerve, can occur, but serious neurologic sequelae are unusual.<sup>21,29,30</sup> Papilledema seems to be more common in children.<sup>32</sup> Most cases resolve spontaneously with complete recovery. However, serious complications and death do occur, probably resulting from larger numbers of migrating larvae or migration of larvae into critical parts of the brain.<sup>22,29</sup>

## PATHOGENESIS AND IMMUNOLOGY

The hallmark of this infection is an eosinophilic CSF pleocytosis. This is the result of larvae migrating through the CNS. Death of the parasite in the CNS also may contribute to the eosinophilic response. Since the human is not a normal host, it is extremely rare for an adult worm to be found in the lungs of humans.<sup>33</sup> An episode of infection does not confer immunity.<sup>9</sup>

## DIAGNOSIS

Finding high numbers of eosinophils in the CSF and travel to an endemic area should suggest eosinophilic meningitis (see Chapter 125). Low numbers of eosinophils can be seen in a variety of conditions, but finding greater than 10% eosinophils in the CSF should suggest this disease.<sup>34</sup> Typically, the CSF shows 100 to 5000 leukocytes per microliter, 10% to 90% of which are eosinophils.<sup>29</sup> The CSF protein is usually elevated, but the glucose is normal or mildly lowered.<sup>29</sup> A peripheral eosinophilia is not a consistent finding.

The differential diagnosis of eosinophils in the CSF should include other helminthic diseases, in particular gnathostomiasis and cysticercosis.<sup>34</sup> *Gnathostoma spinigerum* is also a cause of eosinophilic CSF pleocytosis in areas of Southeast Asia that are endemic for *A. cantonensis* (see Chapter 106).<sup>35</sup> *G. spinigerum* is not specifically neurotropic like *A. cantonensis*, involving the nervous system by random migration. The disease produced is characterized by nerve root pain, paraplegia, spinal cord lesions, xanthochromic CSF, and a much higher mortality rate. In addition, an ascarid parasite of raccoons, *Baylisascaris procyonis*, has rarely been the cause of eosinophilic meningoencephalitis in humans.<sup>36</sup> Certain nonparasitic agents, such as coccidioidomycosis and lymphomas of the CNS, can also be associated with an eosinophilic pleocytosis.<sup>34</sup>

Since paresthesias are common in eosinophilic meningitis, other illnesses causing paresthesias in the tropics need to be considered. Poisonings due to certain insecticides and ingestion of toxic fish or shellfish (e.g., ciguatera) can produce paresthesias.<sup>29</sup> The latter agents would generally not cause a classic aseptic meningitis picture.

Headaches frequently will improve dramatically after a lumbar puncture.<sup>29</sup> Ventricular dilation can occasionally be seen and is probably due to a transient communicating hydrocephalus caused by inflammation of the arachnoid decreasing the resorption of CSF. It is rare, but *A. cantonensis* larvae have been observed in the eye<sup>37</sup> and CSF.<sup>23,38</sup> A larger-bore needle

used for spinal taps is thought to account for the increased number of larvae recovered from the CSF of patients in Taiwan.<sup>23</sup> A computed tomography (CT) scan of the brain in eosinophilic meningitis is generally nonspecific.<sup>39,40</sup> However, magnetic resonance imaging (MRI) with contrast dye can show meningeal enhancement as well as punctate areas of enhancement in the brain.<sup>41</sup> The usual absence of focal lesions on the CT scan helps distinguish eosinophilic meningitis from the focal lesions observed with neurocysticercosis and gnathostomiasis.<sup>42</sup> Patchy pulmonary infiltrates in the lower lung fields can occasionally be observed on the chest radiograph and presumably are due to migrating parasites.<sup>43</sup> Serology has been hampered by a lack of specificity and by cross-reactivity with other helminths.<sup>44</sup> Purification of antigens and defining the immunoglobulin G subclass antibody response have improved accuracy,<sup>45</sup> but the serodiagnosis of angiostrongyliasis is not routinely available. Elevated levels of immunoglobulin E in serum have been reported.<sup>46</sup>

## TREATMENT

There is no specific treatment.<sup>40</sup> Anthelmintics and corticosteroids have been tried, but it is difficult to assess efficacy when there are no controlled studies and the disease is self-limited. Anthelmintics that cross the blood-brain barrier, such as praziquantel or albendazole, should theoretically work in this disease, but a systemic response to dying worms might make the condition worse.<sup>15,21</sup> Adjunctive corticosteroids or corticosteroids alone in severe cases (i.e., severe encephalitis or cranial nerve damage) might be a consideration since in such settings the inflammatory response might be contributing to

the disease. Corticosteroids are not believed to alter the course of uncomplicated disease.<sup>21</sup>

## PREVENTION AND CONTROL

Prevention is by educating travelers or persons in endemic areas that snails, slugs, freshwater shrimp, and crabs must be cooked, not simply marinated or refrigerated, before they are eaten. Vegetables must be washed if eaten uncooked. Commonly infected mollusks like the giant African land snail *A. fulica* should be handled carefully to avoid contamination of the fingers with larvae. Control of mollusks and planarians and reducing the number of rats are also important measures.

## ■ *Angiostrongylus costaricensis*

### AGENT

*A. costaricensis* was first described from Costa Rica in 1971<sup>47</sup> and has a life cycle similar to *A. cantonensis* in that rodents are the definitive host and mollusks are intermediate hosts.<sup>48</sup> *A. costaricensis*, however, develops into its adult form in the mesenteric arteries of rats. The most important rat is the cotton rat (*Sigmodon hispidus*).<sup>48</sup> Humans are abnormal hosts; thus, the parasite is unable to complete its life cycle, dying in the gastrointestinal tract.<sup>47</sup>

### EPIDEMIOLOGY

Human infection occurs predominantly from southern Mexico to Argentina and in Costa Rica. The clinical disease

# *Angiostrongylus costaricensis*\*

*Angiostrongylus* spp.

■ *Angiostrongylus costaricensis*

■ *Angiostrongylus cantonensis*

had been recognized in Costa Rica in the 1950s before *A. costaricensis* was described. Following its description in 1971,<sup>47</sup> abdominal angiostrongyliasis has been reported from Honduras, Venezuela,<sup>48</sup> Martinique, Dominican Republic, Puerto Rico,<sup>49</sup> Argentina, Brazil,<sup>50</sup> Nicaragua,<sup>51</sup> and the United States.<sup>52</sup> A few apparently autochthonous cases have been reported from the United States (Los Angeles)<sup>52</sup> and Africa (Congo).<sup>53</sup> Parasites have been found in rodents in Colombia<sup>54</sup> and Panama<sup>55</sup> without reports of human cases.

At least 12 species of rat and one coati have been shown to be naturally infected.<sup>56</sup> The rat passes first-stage larvae in its feces for up to 8 months.<sup>48</sup> A mollusk intermediate host feeds on the feces of the rat and the larvae transform into infectious third-stage larvae in the mollusk. The mode of transmission to humans is not established. It is assumed that infectious larvae from a molluscan intermediate host, such as the slug *Vaginulus plebeius*, contaminate water or vegetation with infectious larvae, which are inadvertently consumed by humans.<sup>48</sup> Although this particular slug is not indigenous to the continental United States, it has been found on imported produce and flowers.<sup>52</sup> Most human cases have been described in children between the ages of 6 and 13 years.<sup>57</sup> Higher, rather than lower, socioeconomic status is more common.<sup>57</sup> In general, males outnumber females by 2:1.

## DISEASE

The incubation period for abdominal angiostrongyliasis is not known, but is estimated to be 3 to 4 weeks.<sup>52</sup> Clinical findings tend to mimic those of appendicitis<sup>57</sup> or an inflamed Meckel's diverticulum.<sup>52</sup> Patients have fever, nausea, vomiting,

and abdominal pain. The abdominal pain is frequently localized to the right lower quadrant.<sup>56</sup> Occasionally a painful mass in the right lower quadrant can be noted on rectal examination.<sup>57</sup> The symptoms are generally more indolent than those typical of acute appendicitis. Patients tend to have recurrent episodes over several months. Surgical exploration on the suspicion of appendicitis is frequently observed. Complications can be abscess formation, obstruction, and infarction of the bowel.<sup>49</sup> A few deaths have been reported.<sup>57</sup> Occasionally, the testicular artery can be involved, but this diagnosis is generally not made before surgery, which is usually done for a suspected torsion.<sup>57,58</sup>

## PATHOGENESIS

In humans, the parasite usually confines itself to the abdominal cavity; it is rare for parasites to be found outside the gastrointestinal tract. Inadvertent ingestion of slugs, either chopped up in salads or on vegetation contaminated with their mucous secretions, can accidentally allow infectious third-stage larvae into the gastrointestinal tract of humans. The larvae eventually enter the mesenteric arteries where they mature into adults. The adult parasite in the mesenteric arteries can cause arteritis, thrombosis, infarction, and gastrointestinal hemorrhage.<sup>59</sup> Eggs from adults can lodge in capillaries, producing an inflammatory reaction within the intestinal wall. The eggs do not hatch, but degenerate and cause an eosinophilic granulomatous reaction.<sup>60</sup> The resultant histopathologic changes could be suggestive of an allergic granulomatous angiitis (Churg-Strauss vasculitis).<sup>49</sup> Transmission between humans does not take place. The parts of the intestinal tract usually

involved are the terminal ileum and appendix, but other parts of the intestine and occasionally the regional lymph nodes can be involved.<sup>47,57,60</sup>

## DIAGNOSIS

There are no diagnostic tests other than to demonstrate the parasite or its eggs in tissue. Most patients have a leukocytosis, an observation also common in appendicitis, but suspicion of this parasite should be raised when there is an associated eosinophilia on the peripheral blood smear. The eosinophilia can range from 11% to 82% with a leukocytosis of 10,000 to 50,000 white blood cells per microliter.<sup>48,57</sup> The worms usually localize to the mesenteric arteries of the ileocecal region, and radiologic examination of the gastrointestinal tract may show bowel edema and spasticity in that area.<sup>56,57</sup> Stool examination will reveal no forms of *A. costaricensis*. However, a stool examination for parasites is reasonable since *Enterobius vermicularis* could cause similar changes.<sup>52</sup> Human anisakiasis or visceral larva migrans due to *Toxocara* spp. could also mimic abdominal angiostrongyliasis.<sup>61</sup> Several serologic tests have been described, but they are not readily available and not of much clinical use.<sup>62</sup>

## TREATMENT

No specific medical treatment is known. Surgical treatment for acute intestinal inflammation may be necessary. The use of anthelmintics has not been systematically studied, but thiabendazole or diethylcarbamazine has been suggested.<sup>57</sup> Acute episodes can be uncomplicated and resolve spontaneously. The prognosis is generally good.

## PREVENTION AND CONTROL

Avoidance of slugs and the ingestion of raw food and water that might be contaminated by imperceptible slugs or slime from slugs are the cornerstones of prevention and control. Control of rats is important in preventing the spread of this parasite.

# Other Tissue Nematode Infections

YEZID GUTIERREZ

## INTRODUCTION

This chapter deals with a variety of nematodes inhabiting the tissues of humans, producing diseases of practical importance, though encountered infrequently in general medical practice. These infections are all zoonotic and accidental in humans, thus the paucity of patients with these afflictions. Some have a tropical distribution, others are found indiscriminately in tropical and temperate zones, and as of today none is known to behave opportunistically in immunocompromised hosts. Some infections, for example, those produced by anisakid worms, are of paramount regional importance in areas such as Japan where they are part of physicians' daily practice.<sup>1</sup>

This chapter is organized somewhat phylogenetically for reasons of economy of space. The biology is discussed for each group of organisms, and individual differences are outlined under each nematode, when considered medically relevant or when necessary for a better understanding of that parasite.

## RHABDITIDA

***Halicephalobus (Micronema), Rhabditis, Pelodera, Turbatrix, and Diploscapter***

The Rhabditidae are a group of saprophytic, free-living nematodes found in soil, water, and decomposing matter, including the genus *Strongyloides* (see Chapter 111), the most important from the medical point of view. Members of the genera *Halicephalobus (Micronema)*, *Rhabditis*, *Pelodera*, *Turbatrix*, and *Diploscapter* have been sporadically described as parasitizing humans and animals, and *Halicephalobus* has resulted in fatal infections. In general, Rhabditidae have direct life cycles in their natural habitats, where males and females produce eggs that hatch, releasing larvae that develop into adult worms. One exception is *Strongyloides*, which in addition to its free-living development, has a parthenogenetic parasitic phase in the small intestine of some vertebrate hosts, including humans.

## *Halicephalobus (Micronema)*

Excluding *Strongyloides*, *Halicephalobus* is the most important of the free-living nematodes because it causes infections in humans of which at least three fatal ones have been reported, all in North America.<sup>2-4</sup> The fatal human cases were the result of central nervous system (CNS) involvement (meningoencephalitis) in two cases, and in the third, of the CNS plus other viscera.

The infection was acquired by one child after an unfortunate accident in a manure-spreading machine, which resulted in lacerations of the face, fractures of the mandible, penetrating chest and abdominal wounds, and lacerations of the buttocks and thigh with fracture of the femur. Meningoencephalitis developed after 18 days in the hospital and he died 6 days later. Microscopic examination of the CNS revealed numerous nematodes (Fig. 106-1) in various stages of development, including eggs, some with a developing embryo.<sup>2</sup> In another instance, a middle-aged man developed meningoencephalitis and died within 3 weeks. Similarly, microscopic examination of the brain demonstrated female nematodes in the tissues developing parthenogenetically. How this patient acquired the infection is unknown.<sup>3</sup> A third man admitted to a Washington, D.C., hospital, chronically ill, with bilateral decubitus ulcers in the buttocks, died within 10 days of hospitalization. Autopsy revealed similar lesions and nematodes in the CNS, heart, and liver.<sup>4</sup> In the first two cases, the parasites were identified as *Micronema deletrix*, in the third only as *Micronema*, with the suggestion that species identification is somewhat presumptive because of difficulties in speciation.<sup>4</sup> Recently, the genus and species of these free-living nematodes invading the tissues of humans and animals was renamed *Halicephalobus (Micronema)* and the species *gingivalis (deletrix)*.<sup>5</sup>

## *Rhabditis*

Species of *Rhabditis* have been encountered sporadically in the stools and urine of humans,<sup>6-9</sup> but the consensus is that these are usually due to contamination of the stools before the sample for examination is taken. The worms in the fecal sample are just developing as they do under natural conditions in decaying matter. A recent case in Brazil<sup>10</sup> in a 5-month-old child with gastrointestinal symptoms appears genuine. The patient recovered after treatment with thiabendazole.

## *Pelodera*

*Pelodera strongyloides* is found in dogs, cattle, sheep, and horses, causing sometimes significant dermatitis; in lemmings and murid rodents it is found in the conjunctival sac, where it produces no ill effects. Three human infections, one in an 11-year-old European girl,<sup>11</sup> another in a 6-month-old infant girl in the United States,<sup>12</sup> and a third in a 20-year-old man,<sup>13</sup> are known, but it is possible the infection is not diagnosed in most cases. The larvae (dauer larvae) of the parasites are in the skin, producing pruritic papular lesions that are difficult to treat. The larvae do not develop and remain as such; rather, they probably feed on tissue and desquamated cells.<sup>1</sup> The infection of the European child who had an extensive dermatitis

**FIGURE 106-1** *Halicephalobus* in brain. A, View showing some nematodes (arrows), and areas of inflammatory infiltrate. (H&E stain,  $\times 70$ .) B, Higher magnification of nematode. (H&E stain,  $\times 450$ .)

(Fig. 106-2) was acquired from a pet puppy that succumbed to the infection. The U.S. infant presented with failure to thrive and improved after her infection was treated with hydrocortisone lotion 0.5% three times a day. The 20-year-old man was cured with oral thiabendazole. The relationship between the parasitic infection and failure to thrive remains obscure. The diagnosis is made by study of the dauer larvae recovered in skin scrapings or in tissue sections of biopsy specimens.<sup>1</sup>

#### *Turbatrix* and *Diploscapter*

*Turbatrix aceti*, known as the vinegar eelworm, has been found in the vagina of healthy women who used vinegar for douching.<sup>14</sup> Reported rare infections of the urinary bladder are also known, producing no symptoms.<sup>15</sup> *Diploscapter coronata* has been found in the stomach of achlorhydric patients and in the urine of others.<sup>16,17</sup> It is believed that the nematode is a facultative parasite of humans. The diagnosis is made by recovery of the worms and their specific identification.

### STRONGYLIDA

#### *Trichostrongylus*, *Mammomonogamus*, *Oesophagostomum*, and *Ternidens*

The Strongylidae are generally known as the hookworms, a large group of parasitic nematodes found in the intestine, lower and upper respiratory tract, blood vessels, and other

sites. The striking morphologic characteristic of the group is the presence of a bursa in the posterior end of the males, thus the other common name of bursate nematodes.<sup>1</sup> The important human parasites of the Strongylidae belong to the genera *Ancylostoma*, *Necator* (see Chapter 110), and *Angiostrongylus* (see Chapter 105), because they have species that produce important morbidity and mortality. Other genera, such as *Trichostrongylus*, *Mammomonogamus*, *Oesophagostomum*, and *Ternidens*, have species responsible for zoonotic infections diagnosed sporadically, or infections endemic in restricted geographic areas, or with low prevalence rates. The general life cycles of these parasites are either direct, in which case eggs passed in the stools produce larvae in the soil; larvae enter the skin of the host, and via blood reach the lungs and the intestine where they mature (*Ancylostoma* and *Necator*); or indirect, in which an intermediate host, usually a slug or a snail, ingests the larvae evacuated with the feces, and on ingestion of the snail by the final host the larvae migrate and grow in their respective location (*Angiostrongylus*).

#### *Trichostrongylus*

In terms of prevalence in humans, *Trichostrongylus*, a nematode found embedded in the intestinal mucosa of herbivorous animals worldwide, is the most important of the four strongylids discussed here. Eggs are produced and evacuated with the feces into soil, where they mature rapidly and hatch,

**FIGURE 106-2** *Pelodera strongyloides* in skin. A, View of a section of skin illustrating the granulomatous inflammation. (H&E stain,  $\times 140$ .) B, Two well-formed granulomas containing larvae. (H&E stain,  $\times 280$ .) (Courtesy of PC Beaver, PhD, School of Public Health and Tropical Medicine, Tulane University, New Orleans. In Ginsburgh B, Beaver PC, Wilson ER, et al: Dermatitis due to larvae of a soil nematode, *Pelodera strongyloides*. *Pediatr Dermatol* 2:33, 1984.)

producing larval stages that become infective in soil. The infection is acquired by ingestion of larvae with soil, or more commonly with infected vegetation (grass).<sup>1</sup>

*Trichostrongylus* has many members, difficult to speciate, of which at least a dozen have been found in humans. *T. orientalis*, *T. colubriformis*, *T. vitrinus*, *T. axei*, *T. instabilis*, and *T. probolurus* are responsible for the majority of infections. The distribution is practically worldwide, but the places with the highest number of infections are the Middle East, the former southern Soviet republics, India, North Africa, Southeast Asia, Japan, Siberia, Central Africa, and central and southern China. Cases have been reported in Australia,<sup>18</sup> the United States,<sup>19</sup> and South America.<sup>20</sup> Rates of prevalence have been as high as 69% in parts of Iran,<sup>21</sup> 40% in some villages in Japan,<sup>22</sup> and 25% in some localities of Iraq.<sup>23</sup> In southern Sudan there was a prevalence of 2.5% among school children.<sup>24</sup>

As stated previously, the male and female worms are embedded in the small intestinal mucosa, where, if of sufficient number, they are capable of producing trauma with desquamation of the mucosa and hemorrhages. Peripheral eosinophilia can be as high as 71% of 35,750 white blood cells.<sup>19</sup> Some patients have small amounts of blood in the stools, especially in those passing between 100 and 400 eggs per gram of feces.<sup>25</sup> The diagnosis is made in stool samples by

identification of the characteristic eggs. Because of the resemblance of *Trichostrongylus* eggs (Fig. 106-3) to hookworm eggs, the diagnosis is often not made. *Trichostrongylus* eggs are larger than those of the hookworm, are slightly more elongated, and have a thicker wall.<sup>1</sup>

### *Mammomonogamus*

Members of the genus *Mammomonogamus* are parasites of the upper respiratory tract of cats and cattle, in which they produce a disease known as “gapeworm” infection. The life cycle and thus the mode of transmission are unknown.<sup>1</sup> In humans, fewer than 100 infections are known, most of them in tropical America, including Brazil,<sup>26</sup> Martinique,<sup>27</sup> Puerto Rico,<sup>28</sup> Guadeloupe,<sup>29</sup> Saint Lucia, Trinidad, Jamaica,<sup>30</sup> other Caribbean islands, and the Philippines. One case has been reported from Korea.<sup>31</sup> Instances of mammomonogamiasis have occurred in tourists returning to Europe, the United States,<sup>30,32,33</sup> Australia,<sup>34</sup> and Canada,<sup>35</sup> after travel to the endemic areas. The species infecting humans is generally considered to be *M. laryngeus*.

The main clinical manifestation in humans is a dry, persistent cough, sometimes with hemoptysis and asthma, often at night, produced usually by a single pair of worms firmly attached to the tracheal mucosa, and at least in one

**FIGURE 106-3** *Trichostrongylus* sp. egg in stool sample. (Unstained,  $\times 450$ .)

instance within a cyst.<sup>36</sup> The patient from Korea is reported to have many pairs of worms, but the number is not stated.<sup>31</sup> Some patients have complained of weight loss,<sup>34</sup> pleuritic pain,<sup>32</sup> or nausea.<sup>37</sup> The worms are sometimes expectorated by the patient after a violent bout of coughing, revealing a female of about 1 cm in length and a male of about 4 mm permanently attached to the midbody of the female; they somewhat resemble the letter Y and are red in color (Fig. 106-4). The patient usually brings the expectorated worms to the physician, who should recognize them as worms and submit them for proper identification. In other instances, the patient presents for the

**FIGURE 106-4** *Mammomonogamus laryngeus*; adult worms in copula. Note the characteristic configuration of a Y. (Courtesy of JS Nosanchuk, MD, Department of Pathology, Tompkins Community Hospital, Ithaca, NY. In Nosanchuk JS, Wade SE, Landolf M: Case report of and description of parasite in *Mammomonogamus laryngeus* [human syngamiasis] infection. J Clin Microbiol 33:998, 1995.)

persistent cough and is examined with a bronchoscope, allowing the physician to see and retrieve the worms. Once the worms are removed (as stated, most patients harbor only a single pair of worms), the symptoms disappear. Examination of the worms by a knowledgeable individual provides an accurate diagnosis.<sup>1</sup>

### *Oesophagostomum*

Most species of *Oesophagostomum* are parasites of monkeys and apes, but a few occur in swine and sheep and thus they are zoonotic infections. One species, *O. bifurcun*, appears to occur naturally in humans, because in the areas of endemicity—northern Togo and Ghana—there are not enough monkeys to serve as reservoirs of the infection and maintain the level of prevalence that occurs in humans.<sup>38,39</sup> Human infections are reported mostly from Africa: Uganda,<sup>40</sup> Kenya,<sup>41</sup> Ivory Coast,<sup>42</sup> Ethiopia,<sup>43</sup> Sudan,<sup>44</sup> Guinea,<sup>45</sup> Nigeria,<sup>46</sup> and Northern Togo and Ghana, where the bulk of the infections are found.<sup>30,47,48</sup> Isolated cases are known in Brunei,<sup>49</sup> Malaysia,<sup>50</sup> Indonesia,<sup>51</sup> Brazil,<sup>52</sup> and Nova Scotia, Canada, where *O. venulosum* eggs were found in the stools of nine siblings.<sup>53</sup>

Surveys in northern Togo have found that *O. bifurcun* occurs more often in women than in men, and it is estimated that more than 100,000 people are infected in the country, with a prevalence of the infection between 30% and 40% in the population above 5 years of age.<sup>38</sup> Other species infecting humans are *O. apiostomum*, *O. stephanostomum*, and *O. aculeatum*, in other geographic areas.

The adult worms live attached to the mucosa of the colon; eggs are evacuated with the stools, mature in soil, and produce larvae that enter the host via the mouth. In the large intestine, the larvae enter the wall of the viscus, where they grow in an abscess-like cavity (Fig. 106-5). Once maturity is reached, the worms leave the abscess and attach to the colonic mucosa. The lesions (abscess) produced by the worms during their development in the colonic wall are visible grossly as nodules (“nodular worms”) about 1 to 2 cm in diameter. Sometimes the nodules are found toward the peritoneal surface, and in heavy infections the parasites can be recovered from the omentum, the surface of the kidney, the spleen, and other viscera. These lesions are responsible for the symptoms and signs of the infection, and sometimes the nodules push into the abdominal wall, where they are seen as an indurated, well demarcated, painful tumor; one commonly found around the periumbilical area is known as “Dapaong tumor.”<sup>39</sup>

The clinical manifestations are commonly those of an abdominal mass, sometimes large or painful; others present with acute intestinal symptoms, often of obstruction, due mostly to peritoneal adhesions. Asymptomatic persons, mostly children, may present because of a painless or a disfiguring abdominal mass.<sup>40</sup> The assessment of preclinical and clinical cases has improved with the use of ultrasound.<sup>54–56</sup> In acute cases, the treatment is often surgical, and the diagnosis is usually made by the surgical pathologist during the gross or microscopic examination of the removed specimen. In tissue sections, the worms are easily recognized as *Oesophagostomum*, but the species in question cannot be ascertained. Only study of male worms in toto allows the classification of the species.<sup>1</sup> In asymptomatic cases, the infection with *Oesophagostomum* is made by morphologic identification of hatched larvae in coprocultures, because the eggs in the stools are indistinguishable

**FIGURE 106-5** *Oesophagostomum* sp. in human colon. A, View of abscess in the wall of the colon, showing sections of the parasite. (H&E stain,  $\times 22$ .) B, The wall of the abscess and sections of the worm. (H&E stain,  $\times 70$ .)

from those of hookworms.<sup>57</sup> An enzyme-linked immunosorbent assay (ELISA) produced much cross-reactivity with other parasites, but if made specific for detection of IgG<sub>4</sub> it gave a 95% positivity.<sup>58</sup> A PCR assay for specific amplification of DNA of *O. bifurcum* gave better results.<sup>59</sup> Albendazole, used in the cases from Togo and Ghana, was found effective in mixed infections with hookworms against both parasites.<sup>60,61</sup> Pyrantel pamoate was effective against *Oesophagostomum* but not against the hookworms.<sup>61</sup>

### *Ternidens*

One species of this genus, *Ternidens deminutus*, has been implicated in human infections.<sup>62</sup> This parasite has many similarities with *Oesophagostomum*, both morphologically and biologically: it also inhabits the colon where ulcerations and nodular lesions are seen, although a cause-effect relationship between the worms and the lesions remains obscure.<sup>63</sup> The life cycle of *T. deminutus* is mostly unknown, and the mode of infection in humans and animals remains a mystery. Experiments in humans with penetration of larvae through the skin have failed, and thus the existence of an arthropod intermediate host has been postulated.<sup>63</sup> *Ternidens* is usually a parasite of monkeys in Africa, India, and Indonesia; human infections have been recorded only in southeastern Africa,<sup>64</sup> especially Zambia and Zimbabwe, where most of the studies

on this parasite have been carried out. The prevalence in the general population in Zambia and Zimbabwe is variable depending on the area studied, with the highest incidence being 87%.<sup>64</sup>

The symptoms produced by *Ternidens* are not well characterized, and it seems that most patients are asymptomatic. Intestinal blood loss is slight, and anemia does not develop; eosinophilia has not been detected, and although diarrhea has been observed in animals, it has not occurred in humans.<sup>64</sup> The lack of symptoms is likely due to the low number of worms present in the colon: eight worms in a few cases, most harboring three to five. Thiabendazole and pyrantel pamoate have been used to treat patients, curing about 90% of infections.<sup>65,66</sup> The diagnosis is made in stool samples by recognition of the eggs, which are easily mistaken for hookworm eggs; careful measurement of the eggs allows proper identification.

## ASCARIDINA

### *Anisakis*, *Pseudoterranova*, *Baylisascaris*, and *Lagochilascaris*

The Ascaridinae are one of the largest groups of nematodes, with one to several species found in each vertebrate species. Many genera are known in this group including *Ascaris lumbricoides* (see Chapter 109) and species of

*Toxocara* (see Chapter 103).<sup>1</sup> Other species of the Ascaridinae produce zoonotic infections in humans, such as *Anisakis*, *Pseudoterranova*, *Baylisascaris*, and *Lagochilascaris*, some of which—the anisakids—are of paramount importance in certain geographic areas.<sup>67,68</sup>

In general, members of the Ascaridinae are large parasites, for example, species of *Ascaris*, which can be about 35 cm long and inhabits the small intestine of humans and other animals. Most species have direct life cycles: Eggs are evacuated with the fecal mass of the host, and the eggs mature in soil to infective stages. After ingestion of infective eggs by a new host, the eggs release larvae that migrate to the lungs and back to the intestine, where they develop into adults.<sup>1</sup> Other species have indirect cycles: *Anisakis* and *Pseudoterranova*, parasites of marine mammals, have squid and fish as intermediate hosts<sup>69</sup>; and species of *Baylisascaris*, nematodes found in the intestine of raccoons, skunks, bears, martens, and other carnivores, have small rodents, birds, and many other small vertebrates as their intermediate hosts.

### *Anisakis* and *Pseudoterranova*

Anisakiasis (“herring worm disease”) and pseudoterranoviasis (“cod worm disease”) generally present clinically in a manner that is indistinguishable from one another, and thus they are referred to simply as “anisakiasis.” An apparent confusion in the medical literature has occurred because the names of the parasites have changed several times as knowledge of their relationships has increased and their classification improved.<sup>70</sup> The genus *Anisakis* has two important species, *A. simplex* and *A. physeteris*, previously known in their larval stages recovered from human infections, as *Anisakis* larva types I and II, respectively.<sup>69</sup> They are parasites of whales (Cetacea), seals, sea lions, walruses, and other Pinnipediae. The genus *Pseudoterranova* (known in the past as *Ascaris*, *Porraceum*, *Terranova*, and *Phocanema*) has one important species complex, *P. decipiens*, which consists of seven species impossible to differentiate based on the morphology of their larval stages.<sup>71</sup> This genus is parasitic exclusively of members of the Pinnipediae.<sup>69,71</sup> Since all these names are found in medical journals and textbooks, they are mentioned here only for clarification. Specific names should be used for the parasite, or for the disease, only when the larva recovered from humans is conclusively identified by competent taxonomists. Pathologists should use the generic “anisakid” to be precise and *Anisakis* or *Pseudoterranova* only when they identify either genus in tissue sections or on the recovered larva. In tissue sections, the larva is rarely cut in such a manner that it reveals structures that make separation of these two genera possible.<sup>1</sup> Clinicians studying patients suspected of suffering from anisakiasis based on serologic or skin tests using larval antigens should never refer to the patient as having a specific disease or infection (e.g., anisakiasis due to *Anisakis simplex*). There is too much serologic cross-reactivity among the different species of larvae and even much more uncertainty as to the real culprit for the reaction to an applied allergen.

As stated, anisakid worms inhabit the stomach of their final hosts, where they bury the anterior portion of their bodies into the gastric mucosa and grow attached to it. Eggs are produced and evacuated with feces into seawater where they mature, and each develops a larva that hatches to become part

of the zooplankton. Larvae are ingested by squid and several other species of macro-invertebrates, where they develop into infective larvae. Ingestion of these infected intermediate hosts by smaller fish allows the larvae to grow further and remain in the infective stage. Ingestion of infected squid, macro-invertebrates, or fish by the final hosts produces the infection in the stomach.<sup>1</sup> Humans become infected by ingestion of raw marine fish in delicacies such as sushi, sashimi, oka, poisson cru, ceviche, and so on.<sup>70</sup> The infection is thus more important in Japan, where the number of cases reported is in the thousands, because raw marine fish is a daily staple.<sup>67,68</sup> The infection is found sporadically in other places where consumption of raw fish has become fashionable, or where fish is a large part of the diet and occasional larvae are not killed in undercooked dishes. A small number of cases have been diagnosed in the United States<sup>72–74</sup> and South America.<sup>75</sup> A larger number in Europe,<sup>76</sup> especially in the Netherlands, where the infection was first recognized in the early 1960s, was traced to the consumption of raw herring<sup>77–79</sup>; public health measures have controlled the infection. In Spain, the disease was recognized in the early 1990s<sup>80</sup> and some cases reported are clinically and pathologically similar to the experience in Japan. However, in Spain an inordinate number of patients with allergies have been considered to have *Anisakis* infection based on serologic tests, IgE determination, skin tests with extracts of *Anisakis simplex* larvae, or antecedents of consumption of raw fish.<sup>81–84</sup> This needs further verification.

Anisakiasis is mostly an infection of the gastrointestinal tract; sometimes ectopic locations are encountered, such as the peritoneal cavity and its organs<sup>67,68</sup> and once the lungs.<sup>85</sup> In the majority of cases, the infection is produced by a single larva, uncommonly by two and rarely by several.<sup>1</sup> The lesion in humans is dictated by the biologic behavior of the parasite, which buries its anterior portion in the gastrointestinal mucosa and tries to develop into an adult.<sup>69</sup> Because humans are abnormal hosts, the parasite does not become an adult, dies as a larva, and elicits an abscess with marked inflammation, edema, and tissue eosinophilia<sup>1</sup> (Fig. 106-6). This abscess may be of sufficient size to be clinically palpated or seen on radiographs as a mass. The lesion is found anywhere in the esophagus, stomach, or small or large intestine. Sometimes the larva perforates the viscus wall and enters the peritoneal cavity, where it dies, producing the abscess (tumor), mostly in the omentum and only occasionally on the surface of the viscera.<sup>67,68</sup> Larvae have been recovered from the peritoneum by surgeons during exploratory laparotomies and in one patient under dialysis in the effluent.<sup>86</sup> Some persons have symptoms of itching or of a scratchy sensation in the mouth or throat during or soon after a meal of raw or insufficiently cooked fish.<sup>74</sup> A sensation of a foreign element (the worm) in the oral cavity makes the person retch and recover the bothersome worm, or expectorate it after a paroxysm of coughing. A good number of the cases of anisakiasis reported in the United States have presented in this manner, produced by *Pseudoterranova*, a worm that apparently has a lesser capacity for tissue invasion.<sup>74</sup> The recovered larva is often submitted to the physician, who should reassure the patient of the benign nature of the condition. In other cases in the United States, a larva has been found in histologic sections of the intestinal wall and correctly diagnosed as *Anisakis*.<sup>72</sup>

Clinically, for diagnostic and therapeutic purposes, anisakiasis is classified as gastric, intestinal, or extraintestinal.<sup>69</sup>

**FIGURE 106-6** *Anisakis* in intestinal wall. A, View of the lesion showing a section of a well-preserved worm. (H&E stain,  $\times 55$ .) B, Another patient with a similar lesion, but a markedly degenerated worm. (H&E stain,  $\times 200$ .)

Often, the clinical presentation is acute; in some it has an indolent course. The main symptoms are abdominal with epigastric pain accompanied by nausea and vomiting. Sometimes the parasite is recovered with the vomitus. Abdominal distention and other clinical and radiographic signs and symptoms of intestinal obstruction may be evident.<sup>69</sup> These are accompanied by diarrhea, followed by normal stools or constipation, and blood and mucus in the stools. A movable, discrete mass may be palpated; and if contrast radiographs are obtained, the mass is easily seen as a defect of the intestinal wall. The mass and the symptoms resolve spontaneously in some instances, the so-called evanescent tumor of the stomach, in places where it has been observed more commonly. Mild fever, leukocytosis, and eosinophilia are almost always present, as is some amount of peritoneal fluid, which is rich in leukocytes and eosinophils. Endoscopic examination of the stomach and duodenum may reveal a red, bleeding, often ulcerated lesion, sometimes with the worm at the center with its anterior portion embedded in the mucosa and the rest of the body extending into the lumen. If the worm is detected, it can be pulled out with forceps; this usually suffices as treatment of the condition.<sup>67,68</sup> In radiographs the worm may be also seen as a negative image in the contrast media, in spite of the relatively small size of the parasite, 2.0 to 3.5 cm  $\times$  1 to 2 mm. Worms in the intestine are more difficult to retrieve endoscopically, and depending on how acute the symptoms are, the patient is often operated on for removal of the segment of inflamed bowel. The pathologist may find the

worm on the open bowel segment grossly or sometimes on microscopic examination.<sup>1</sup>

Extraintestinal anisakiasis is difficult to diagnose clinically and usually requires exploratory surgery for treatment and pathologic diagnosis. The inflammatory mass is usually less than 4 cm in diameter and located anywhere in the abdominal cavity, from where it should be removed. Ectopic anisakiasis (those cases in which the worm is found outside the intestine) is rare. At least three cases diagnosed presumptively or based on Western blot have been reported in Japan.<sup>85</sup> The clinical diagnosis is difficult, especially since *Paragonimus*, *Gnathostoma*, *Fasciola*, and *Sparganum* produce similar syndromes. No medical treatment is available or used, since the disease resolves with removal of the worm.

### *Baylisascaris*

Several species of *Baylisascaris* are known throughout the world as intestinal parasites of many lower vertebrates. These ascarids are common in raccoons (*B. procyonis*), skunks (*B. columnaris*), martens (*B. devosi*), bears (*B. laevis*), and other vertebrates; they necessitate an intermediate host, usually small rodents, birds, and many others, for their development.<sup>1</sup> Eggs evacuated with the feces of the final host mature in soil to become infective; following ingestion of eggs by the intermediate host, the larvae are freed in the intestine to produce an infection in all the tissues. The parasites eventually encapsulate after producing severe tissue damage and a high

mortality in these hosts owing to central nervous system involvement.<sup>1</sup>

To date, about a dozen human infections have been reported, mostly in infants, five residing in the northern United States.<sup>87-92</sup> In two of the infants, a 10-month-old and an 18-month-old with Down syndrome, the infection was fatal. The disease in both started with a mild upper respiratory illness, but each soon developed symptoms of CNS involvement as a result of damage produced by the migrating larvae in the brain substance. The 10-month-old infant was lethargic, irritable, obtunded, with lack of spontaneous movements, and practically semicomatose when he was brought to the hospital. The other child also presented with CNS involvement, though of a lesser degree. The laboratory data showed moderate leukocytosis, with 37% and 27% eosinophilia, respectively; the spinal fluid contained 5 and 92 cells, respectively, without pathogenic organisms isolated. One child died 6 days after hospitalization; the other went home in a decompensated CNS state and died 14 months later. The other four infants were brought to the hospital because of several neurologic complaints and were diagnosed as having baylisascariasis based on serologic tests with *B. procyonis* larval antigens in the serum and spinal fluid.<sup>90-92</sup> These patients were treated with thiabendazole, albendazole, ivermectin, and prednisone in different combinations with some response. All four patients left the hospital with severe neurologic sequelae.<sup>90-92</sup> Another case was reported as *Baylisascaris* based on study of a presumably necrotic larva, too degenerated for identification. The presumed larva was eliciting an eosinophilic pseudotumor in the left myocardium that

protruded into the left ventricle and resulted in the sudden death of a 10-year-old boy in Massachusetts.<sup>93</sup>

Examination of the tissues recovered at autopsy of fatal cases shows extensive CNS damage (Fig. 106-7), acute in the infant who died in the hospital and chronic in the infant who died at home. Microscopically, larvae with morphology similar to that of *Baylisascaris* larvae were found, encapsulated in every tissue examined.<sup>1</sup> Although based mostly on circumstantial and epidemiologic evidence the parasite has been called *B. procyonis* in these reports; the true species of *Baylisascaris* responsible for human and most animal infections remains to be determined. Identification of *Baylisascaris* larvae in tissues is based on morphologic characteristics, but the species of *Baylisascaris* is impossible to determine; the best possible interpretation in all cases where sections of the larvae are found in tissues is the generic *Baylisascaris* sp.<sup>1</sup>

Many patients suffering from diffuse unilateral subacute neuroretinitis (DUSN), with or without nematode larva observed in the retina, are said to be suffering from ocular baylisascariasis. Although this may well be the case, there is no direct confirmation for this idea and especially for labeling the parasite specifically as *B. procyonis*. This statement is made despite indirect evidence in animals where production of retinitis occurs in experimental infections with *B. procyonis*. In most of the reported patients, a nematode larva has been visualized in the retina with the slit lamp, and as well as it can be determined, the nematode has a size range consistent with the size of *Baylisascaris* larvae. Since identification of worms based on size alone is not a valid criterion to give a specific name, the role of *Baylisascaris* in the production of diffuse

**FIGURE 106-7** *Baylisascaris* sp. in human brain. A, Gross lesion, consisting of areas of necrosis. B, View of a section of the larva. (H&E stain,  $\times 180$ .) (Courtesy of NS Gould, MD, Department of Pathology, Michael Reese Hospital and Medical Center, Chicago. Case reported in Fox AS, Kazacos KR, Gould NS, et al: Fatal eosinophilic meningoencephalitis and visceral larva migrans caused by the raccoon ascarid *Baylisascaris procyonis*. N Engl J Med 312:1619, 1985.)

unilateral subacute neuroretinitis remains likely but unproven.<sup>1,94</sup>

### *Lagochilascaris*

Fewer than 50 infections in humans due to *Lagochilascaris* are known, and all of them are in Central and South America.<sup>95–99</sup> The species implicated in all known human cases is *L. minor*, the life cycle of which is now partially known, but the manner in which human infections are acquired remains obscure. A related species found in North America, *L. sprengi*, is known to reside in the stomach wall of opossums. Eggs passed with the feces become infective and are ingested by intermediate hosts where the larvae encapsulate. In some instances, the parasites develop into adults in the tissues in which they produce eggs that are evacuated through sinus tracts from the subcutaneous tissues into the skin.<sup>100</sup> Studies with *L. minor* of human origin have demonstrated the existence of an intermediate host.<sup>101–103</sup>

*L. minor* has been found to reside in animals in the upper airways and the oropharynx, and the disease it produces in humans parallels this location and the known development in the animal tissues. The infection is mostly characterized by marked chronic inflammation, edema, and numerous sinus tracts in the neck, face, tonsils (Fig. 106-8), throat, and mastoid

and paranasal sinuses.<sup>104</sup> The appearance of the lesion is that of a large tumor mass. Fever and pain are absent, and the condition usually progresses for several months before the patient seeks medical help. Some complain mostly of sinusitis and cough and sometimes expectorate or pass the worms through the mouth.<sup>105–107</sup> Eggs are usually found in the discharged pus from the sinuses and sometimes in stool samples, where their recognition is difficult because they resemble *Ascaris* eggs.<sup>97</sup> At least two fatal cases have resulted from migration of the worms to the brain, causing encephalitis, and to the lungs, producing abscesses.<sup>108,109</sup> No studies of drugs for treatment of the infection in humans have been carried out. Treatment of one case with surgical drainage of the abscesses and administration of cambendazole and levamisole did not improve the patient's condition, whereas a course with ivermectin resulted in complete remission.<sup>110</sup> Another patient treated with thiabendazole was cured.<sup>97</sup>

## SPIRURIDA

### *Gnathostoma*, *Thelazia*, and *Gongylonema*

The Spirurida is a large group of nematodes characterized by having intermediate hosts in their life cycles. The largest superfamily of the Spirurida is the Filarioidea, which comprises

**FIGURE 106-8** *Lagochilascaris minor* in human tonsil. A and B, Views of the abscess, showing cross-sections of the worms. (H&E stain,  $\times 70$  and  $\times 180$ , respectively.) (Courtesy of MD Little, PhD, School of Public Health and Tropical Medicine, Tulane University, New Orleans. In Botero D, Little MD: Two cases of human *Lagochilascaris* infection in Colombia. Am J Trop Med Hyg 33:381, 1984.)

all filarial worms, some of which produce important diseases in humans (see Chapters 98–101). The intermediate hosts of those species important to humans are arthropods for filarial worms, and *Thelazia*, and fresh water fish for *Gnathostoma*. The Filarioidea has some species exclusively parasitic in humans, but the majority of the species in this group occur naturally in animals, producing zoonotic infections in humans. Infections with *Gnathostoma* are becoming more common in some geographic areas as awareness of the disease increases. *Thelazia* and *Gongylonema* infections are rare, but they continue being reported.<sup>1</sup>

### *Gnathostoma*

More than 10 species of *Gnathostoma* are known as parasites of wild and domestic cats and other carnivores worldwide, each with its own geographic area of distribution. The species causing most human infections is *G. spinigerum*; rare cases due to *G. hispidum*,<sup>111</sup> *G. doloresi*,<sup>112</sup> and *G. nipponicum* are known in Southeast Asia. In Mexico and Ecuador the species is thought to be *G. binucleatum*,<sup>113,114</sup> and a case apparently produced by *G. malaysiae* was reported recently.<sup>115</sup> Gnathostomiasis is an infection that occurs in populations with a taste for raw freshwater fish in their diet. Thus, Japan and Southeast Asia in the Old World and Mexico and Ecuador in the Americas are the main foci of infection. Imported cases occur in the United States, Europe, and elsewhere. Isolated cases are known in other parts of the world.

In their natural hosts, the parasites are coiled in tumors formed in the stomach wall; eggs are evacuated with the feces and in water produce larvae that are ingested by small crustaceans, *Cyclops*, where the larvae develop further. The infected crustaceans are ingested by small freshwater fishes, frogs, snakes, and other vertebrates, where the larvae become infective and locate in the muscles. An inappropriate definitive host ingesting an infected animal will harbor the larva in its tissues and thus act as paratenic hosts. Ingestion of any of these hosts by carnivorous definitive hosts produces the

infection in the stomach. If humans, not natural hosts, ingest the infective larvae, the larvae do not develop into adults (paratenism) but rather remain as larvae and migrate through the tissues, producing larva migrans, either cutaneous or visceral, depending on their location. Thus, any organ can be compromised, and the result can be devastating clinical syndromes, some of which are fatal.<sup>1</sup>

The distribution of human gnathostomiasis is mainly Thailand, India, Japan, China, Malaysia, the Philippines, and Vietnam.<sup>116</sup> Cases in Sri Lanka,<sup>117</sup> Zambia,<sup>118</sup> Bangladesh,<sup>119</sup> and Vietnam<sup>120</sup> have been recorded recently. Many cases in several foci are now known in Mexico<sup>114,121</sup> and Ecuador<sup>122</sup>; the cases seen in the United States have occurred mostly in Southeast Asian immigrants.<sup>123–126</sup> In humans, the symptoms and signs produced by the worms are protean and difficult to diagnose clinically, because they can compromise any organ system.<sup>1</sup> The larvae probably first reach the liver from the stomach soon after ingestion, and from the liver migrate to almost any other organ.

The symptoms of infection begin after ingestion of a single larva, rarely two or more, and consist of epigastric pain, nausea, and vomiting lasting sometimes 2 to 3 weeks, consistent with penetration of the intestinal wall and migration of the worm. A larva located in the subcutaneous tissues (Fig. 106-9) produces edema and inflammation,<sup>127</sup> seen and felt as an indurated, pruritic, erythematous lesion, sometimes known as Yangtze edema or Shanghai rheumatism, and in the United States as nodular eosinophilic migratory panniculitis. The swelling may resolve, but it will reappear in another location because of the proclivity of the larva for migration in the tissues. If the larva reaches the superficial squamous epithelium, it manifests as cutaneous larva migrans (see Chapter 103).<sup>128</sup> Because of the large size of the parasite, the larva is visible in the skin and can be recovered easily with slight scarification of the stratum corneum.

The most important manifestation of gnathostomiasis is produced by its migration through the CNS, resulting in often fatal syndromes<sup>129</sup> such as radiculomyelitis,<sup>130</sup>

**FIGURE 106-9** *Gnathostoma* sp. in section of human skin, showing the inflammatory reaction and a section of the worm in the subcutaneous tissues. (H&E stain,  $\times 70$ .)

radiculomyeloencephalitis,<sup>131</sup> and subarachnoid hemorrhage.<sup>132</sup> Marked radicular pain is the result of migration of the larva through the spinal root nerves on its way to the spinal canal and brain. The pain lasts 1 to 5 days<sup>129,131</sup> and often is accompanied by paralysis of one or more extremities; paraplegia is often seen, sometimes followed by triplegia and quadriplegia. In the brain, the encephalitis manifests with cranial nerve symptoms, such as palsies, nystagmus, and meningeal irritation. The main clinical characteristic of *Gnathostoma* encephalitis is the migratory nature of the neurologic symptoms. Disappearance and reappearance of symptoms is common and considered characteristic<sup>129</sup>; the laboratory data are usually not helpful. The spinal fluid is often hemorrhagic or xanthochromic and its pressure elevated. Spinal fluid eosinophilia is present in all cases, the number of cells reaching about 500/mm<sup>3</sup>; peripheral eosinophilia is sometimes present.

The other sites where *Gnathostoma* produces disease, in order of importance, are the eye,<sup>126,133,134</sup> lungs,<sup>135,136</sup> and gastrointestinal tract,<sup>137</sup> but almost every organ can be compromised.<sup>1</sup> In endemic areas, the clinical diagnosis is suspected by physicians accustomed to dealing with the infection; in other areas it is difficult. Confirmation of the clinical diagnosis is made by recovery of the larva and study of its morphologic characteristics. Larvae recovered from humans have measured from 2.5 to 12.5 mm in length by 0.4 to 1.2 mm in width. In histologic sections of biopsy specimens, the parasite can be recognized easily to the generic level based on its internal anatomy. More careful studies of the anatomy of the larva in good sections may allow identification of the species on the basis of the size and the nuclei of the intestinal cells.<sup>138</sup>

Serology is often used in the clinical practice to “corroborate” a clinical diagnosis, and various tests are available for the purpose. These tests do not, however, provide definitive proof of the infection,<sup>139</sup> and never do they identify the species

involved because all species of *Gnathostoma* cross-react with each other.<sup>140</sup> Ribosomal DNA sequencing is a more promising tool for speciation of parasites.<sup>113</sup>

### *Thelazia*

A few infections with *Thelazia callipaeda* in China,<sup>141,142</sup> Japan,<sup>143</sup> Korea,<sup>144</sup> India,<sup>145</sup> Russia, Taiwan,<sup>146</sup> and Thailand<sup>147</sup> have been recorded. *Thelazia californiensis* has also produced human infection in California.<sup>148,149</sup> The parasite is a common finding in the conjunctival sac of dogs, rabbits, and other animals. The mode of transmission to humans is unknown, but given that the eggs of the worm are discharged with tears of the infected animals, and that flies are the intermediate hosts, flies must play a role. The symptoms are lacrimation and feeling a foreign body in the conjunctiva. Careful examination of the eye reveals the worms, which can easily be retrieved.<sup>148</sup>

### *Gongylonema*

*Gongylonema* is a parasite of ruminants that occasionally causes accidental zoonotic human infections reported in Europe,<sup>150,151</sup> China,<sup>152</sup> Morocco,<sup>153</sup> Russia,<sup>154</sup> New Zealand,<sup>155</sup> Sri Lanka,<sup>156</sup> and the United States.<sup>157,158</sup> In animals, the worms are located in superficial tunnels buried in the epithelium of the esophagus, the tongue (Fig. 106-10), or other places in the oral cavity; in humans worms have been recovered mainly from similar tunnels in the buccal epithelium, mainly the lips, gums, tonsils, hard and soft palates, and jaw. The worms are seen as small, migrating, threadlike structures under the superficial layers of the squamous epithelium. Humans become infected probably by accidental ingestion of the intermediate host, the cockroach. The eggs of the worm have once been found in the stools of an infected Japanese person in Thailand.<sup>159</sup>

**FIGURE 106-10** *Gongylonema* sp. in section of tongue of infected animal. (H&E stain, ×140.)

## ENOPLIDA CAPILLARIDS

### *Calodium hepaticum* (*Capillaria hepatica*) and *Paracapillaria philippinensis* (*Capillaria philippinensis*)

The capillarids, common parasites of animals, may cause human infection, occurring sporadically, occasionally in clusters, and rarely in large numbers (*P. philippinensis*). The capillarids belong to a larger group, the Trichinelloidea, which includes important parasites of humans such as *Trichinella spiralis* (see Chapter 104) and *Trichuris trichiura* (see Chapter 108). Their distinctive morphologic characteristic is the structure of their esophagus, which is made up of gland-like cells.

#### *Calodium hepaticum*

This worldwide parasite of small rodents, prairie dogs, monkeys, and other animals, produces a type of cirrhosis known as parasitic cirrhosis. The adult male and female worms live in the liver, where they produce eggs that elicit a marked granulomatous reaction (fibrosis) that eventually destroys the worms. The eggs survive; when by predation the host is ingested by a carnivore, the eggs in the liver are digested and evacuated with the feces of the carnivore. In the soil, the eggs become infective for the final hosts, or accidentally for humans; ingested eggs in the new host produce larvae that locate in the liver and mature into adults.

Human infections, totaling fewer than 30 worldwide, have been reported in the continental United States,<sup>160–162</sup> Hawaii,<sup>163</sup> England,<sup>164,165</sup> India,<sup>166</sup> Turkey,<sup>167</sup> Nigeria, South Africa,<sup>168</sup> Mexico,<sup>169,170</sup> Brazil,<sup>171</sup> Italy,<sup>172</sup> Switzerland,<sup>173</sup> Korea,<sup>174</sup> Kosovo,<sup>175</sup> and the former Czechoslovakia.<sup>176</sup> The clinical symptoms are variable, acute or subacute, with manifestations of acute hepatitis that evolve into a picture indistinguishable from visceral larva migrans (see Chapter 103). The only clinical difference with visceral larva migrans is the greater enlargement of the liver in capillariasis, about 2 to 3 cm below the costal margin, compared with 1 cm in visceral larva migrans. The only positive laboratory sign is the marked peripheral eosinophilia.<sup>177</sup> Liver biopsy or autopsy specimens show histologically different patterns of disease, depending on the stage of evolution of the infection. Early, immature worms (Fig. 106-11A), granulomas, and extensive eosinophilic infiltration are present. Later, the adult worms can be identified mixed with numerous eggs, all producing marked granulomatous inflammation and tissue eosinophilia (Fig. 106-11B). The latter stages are characterized by the lack of adult worms, the presence of viable eggs, and marked fibrosis.<sup>1</sup> The outcome of the infection apparently depends on the worm load, with some cases progressing rapidly to severe liver disease and death, others following a chronic course, and still others having remission. At least seven patients have survived. With the triad of leukocytosis, peripheral eosinophilia, and enlargement of the liver disproportionate for *Toxocara* infections, the diagnosis

**FIGURE 106-11** *Capillaria hepatica* in human liver. A, View of section of liver biopsy specimen showing sections of immature worms. Note the scant inflammation at this stage. (H&E,  $\times 200$ .) B, Liver section from another patient with advanced disease. Note the granulomatous inflammation and the presence of eggs (arrows). (H&E stain,  $\times 180$ .)

**FIGURE 106-12** *Capillaria philippinensis* in human intestines. A, View of section of small intestine showing diffuse inflammatory infiltrate and sections of worms. (H&E stain,  $\times 70$ .) B, The inflammatory infiltrate and the worms. (H&E,  $\times 180$ ). Inset: Egg in unstained stool sample. (H&E stain,  $\times 450$ .)

may be difficult clinically, but needle liver biopsy specimens<sup>173,174</sup> or open biopsies<sup>178</sup> provide rapid and accurate identification of the problem in children and sometimes in adults. Two recent cases have been treated with thiabendazole: One patient recovered completely<sup>173</sup>; the other, with more severe disease, developed IgA nephropathy, and 2 years later his condition was stable, though still with severe liver damage.<sup>174</sup>

An important aspect of hepatic calodiasis in humans is the possibility of misdiagnosed spurious infections. If humans ingest liver of infected animals, noninfectious eggs will pass the alimentary canal and can be detected in stool samples.<sup>179</sup> Such ingested and passed eggs cannot be distinguished morphologically from eggs produced during active human infection. In each case in which *C. hepaticum* eggs are found in humans, a second fecal sample should be taken and examined within a few days. Finding eggs in both samples will confirm that there is indeed active infection,<sup>1</sup> not simply intestinal passage of ingested eggs. An immunofluorescent assay for diagnosis, using frozen sections of infected mice liver, has been described.<sup>180</sup>

### *Paracapillaria philippinensis*

The agent of intestinal capillariasis is *P. philippinensis*, a nematode first described in the Philippines in 1964 during an epidemic of gastrointestinal disease that resulted in many deaths.

Later the parasite was placed tentatively in the genus *Aonchoteca*<sup>181</sup> and more recently in the genus *Paracapillaria*.<sup>182</sup> The infection is found in other countries, including Thailand,<sup>183</sup> Iran,<sup>184</sup> Japan,<sup>185</sup> Egypt,<sup>186</sup> Indonesia,<sup>187,188</sup> Korea,<sup>189</sup> India,<sup>190</sup> and Taiwan<sup>191</sup> and in Spain in a traveling Colombian who probably acquired the infection in Colombia.<sup>192</sup> The geographic distribution of intestinal capillariasis is likely to be much larger than is presently known, and infections are probably not being diagnosed because the eggs of *P. philippinensis* are mistakenly identified as *Trichuris* eggs (Fig. 106-12, inset). In autopsy material recovered from patients dying in the Philippines' epidemic, the parasites found buried in the small intestinal mucosa (see Fig. 106-12) were recovered, enabling their recognition as a then new species.<sup>193</sup> The life cycle of the parasite involves small freshwater fish intermediate hosts, which upon ingestion release larvae that grow to adults in the human intestine. Some females lay eggs that mature rapidly in the intestine, produce larvae that enter the mucosa (internal autoinfection),<sup>194</sup> and develop into adults, explaining the large number of worms in infected persons. Other females lay eggs that are evacuated with the feces, and in water become infective and are ingested by the fish intermediate host.<sup>195</sup>

The clinical manifestation of infection is watery diarrhea that does not respond to customary treatment. The patient is usually a 20- to 50-year-old man who becomes infected

while working in the fields, eating raw fish. The patient usually presents days after the beginning of his illness, when the symptoms are more sprue-like. Weight loss due to malabsorption of fats, vitamins, proteins, and carbohydrates is common. Abdominal pain, slight fever, and anorexia are also found, together with emaciation and dehydration.<sup>196,197</sup> Laboratory tests may show slight leukocytosis and eosinophilia; examination of the stools demonstrates the typical eggs, larvae, and sometimes adult worms.<sup>198</sup>

# Enterobiasis

JAMES S. McCARTHY  
THOMAS A. MOORE

## INTRODUCTION

*Enterobius vermicularis*, commonly known as pinworm, is one of the most prevalent intestinal nematodes of humankind. Unlike the other common intestinal nematodes of humans, it does not disproportionately affect residents of tropical climates or populations with poor hygiene or low socioeconomic status. In addition, unlike most other human helminth parasites, the eggs that are deposited on the anal skin are immediately infective and do not require a period in the environment to embryonate. Thus, transmission is largely from person to person. Infection generally results in irritating but not life-threatening perianal pruritus.

## AGENT

*E. vermicularis* is a member of the Oxyuridae class of nematodes. It has recently been proposed that it should be placed in a subfamily of oxyurid parasites, the Enterobiinae, a group that includes the pinworm parasites of primates and some rodents. The status of a new species proposed to infect humans, *Enterobius gregorii*,<sup>1</sup> remains controversial. Some authors suggest that the distinctive morphologic appearance

reported to differentiate this species may instead represent transitional life cycle stages of *E. vermicularis*.<sup>2</sup> Further, no molecular genetic studies have yet established that this separate species indeed exists.

The adult female *E. vermicularis* worm appears as a small, white roundworm, measuring 9 to 12 mm in length and 0.5 mm in width (Fig. 107-1A). It possess a double-bulbed esophagus and a mouth with a cuticular expansion. It has a long, pointed tail and a slit-like vulva on the ventral surface about one third of the distance from the anterior end. The adult male is rarely seen in clinical practice, since it has a much shorter life span and is significantly smaller, measuring 2.5 mm in length and 0.2 mm in width. It is curved along its posterior third and has a blunt caudal excretory-copulatory spicule. A detailed morphologic description of the parasite is available.<sup>3</sup> Parasite eggs are the life cycle stage most readily identified for diagnosis. The characteristic eggs are ovoid and measure  $50 \times 25 \mu\text{m}$ . The eggs are flattened on one side, giving them the classical bean shape (Fig. 107-1B).

## Life Cycle

Adult worms inhabit the lumen of the cecum and appendix. The life span of the adult female is estimated to be between 4 and 10 weeks, while the adult male's is estimated to be only about 2 weeks. Following fertilization, the gravid adult female migrates from the large intestine onto the perianal skin (Fig. 107-2), where she deposits up to 11,000 eggs by uterine contraction and rupture. The sticky eggs adhere to the anal skin and embryonate rapidly over about 6 hours to reach the infective L3 larval stage, still inside the eggshell. The intense pruritus induced by the adult female and the eggs facilitates fecal-oral transfer of eggs. Alternate modes of transmission of infective-stage eggs include fomites and sexual transmission. The minimal interval between egg ingestion and the next egg deposition is between 3 and 4 weeks. The role of reinfection (migration of newly hatched larvae from the anal skin back into the large intestine) remains to be established.

## EPIDEMIOLOGY

Pinworm eggs have been identified in coprolites (fossilized feces) from North and South America dating back as far as around 7800 BC,<sup>4</sup> from Han Dynasty China (206 BC to 220 AD),<sup>5</sup> and from ancient Egyptian mummies (30 BC to 395 AD).<sup>6</sup> Contemporary epidemiologic surveys have documented infection in all populations studied. However, there is a paucity of recent large-scale studies in which the prevalence and intensity of infection has been documented. Furthermore, no recent longitudinal studies have been undertaken to systematically evaluate changes in epidemiology. In a survey of results of 216,275 stool parasitologic examinations undertaken in state diagnostic laboratories in the United States in 1987, 9597 cello tape test results from 35 states were reported with a rate of 11.4% positive results for pinworm being documented.<sup>7</sup> In a number of reports, however, the prevalence of infection in

well-recognized at-risk groups such as residents of orphanages and homes for the intellectually disabled appears to be in decline.<sup>7,8</sup> This likely reflects improved sanitation and living standards in such institutions. Likewise in a report of cellotape test results from a large hospital in New York City in the interval from 1971 to 1986, a decline was observed in both the number of tests undertaken annually, from 248 in 1971 to 38 in 1986, and the frequency of positive tests, from 57 (23%) to 0 (0%), respectively.<sup>9</sup> Whether such results reflect a true decrease in prevalence remains to be conclusively established.

Although it is commonly held that enterobiasis, in contrast to other intestinal helminth infections, is more prevalent in temperate than tropical climates, there is a paucity of contemporary data to support this view. Certainly the parasite has been found throughout the developing and developed world when appropriate diagnostic testing has been undertaken. Like other intestinal helminths, the intensity of infection is overdispersed (aggregated); that is, a small proportion of the population carries a disproportionate worm burden. For example, in one study undertaken in a fishing village in southern India the most heavily infected 25% of study subjects harbored more than 90% of the parasites.<sup>10</sup> In this study, a significant aggregation of infection in household units was also observed. As has also been seen with other intestinal helminths, individuals with heavy infection tend to reacquire a disproportionately high parasite burden after curative treatment.<sup>11</sup>

Well-recognized cofactors for increased risk of *Enterobius* infection include overcrowding, poor sanitation, and lack of water for bathing and washing of hands and clothes. While sexual transmission of the parasite also occurs,<sup>12</sup> this route of transmission is likely to be of low significance. Likewise, although eggs have been identified in household dust, the relative role of fomites in transmission remains to be established. While the potential for nosocomial transmission of the parasite exists, such an occurrence is unlikely in hospital environments where good standards of hygiene prevail.<sup>13</sup>

## DISEASE

The most common clinical manifestation of *E. vermicularis* infection is *pruritus ani*. This is attributable to the expulsion of eggs by gravid females onto the skin of the anus. When very heavy infection is present, an eczematous reaction with bacterial superinfection may occur. While these symptoms certainly favor spread of infection, the mechanism by which egg deposition causes irritation remains unknown. Other clinical manifestations associated with infection include teeth grinding, enuresis, insomnia, nausea, abdominal pain, vomiting, and appendicitis. The association of these manifestations with pinworm infection is unknown, since no well-performed case-control studies have been undertaken. Likewise, the incidence of asymptomatic infection remains unknown. While appendiceal pinworms have been identified in up to 4% of surgical specimens, appendiceal inflammation is not universal in their presence.<sup>14</sup> Furthermore, the role of pinworms in the pathogenesis of appendicitis remains to be defined. Infection of the female genital tract has been well reported, with manifestations including vulvar and cervical granulomas, salpingitis, oophoritis, tubo-ovarian abscess, and peritonitis. Eosinophilic colitis has also been reported and appears to occur early in

infection, since only larvae rather than eggs have been identified in such cases.<sup>15</sup> Rare cases of ectopic infection involving other organs, including the breast, liver, and epididymis, and inguinal hernia have been reported.

## DIAGNOSIS

A diagnosis of *E. vermicularis* infection is almost universally established by demonstrating parasite eggs using the cellotape (unfrosted Scotch tape) test. Although commercially produced tests are available, the test in essence involves preparing a wooden tongue depressor or swab stick with clear adhesive tape, with the sticky side facing outward. This is then applied to the anal skin, the tape removed and placed sticky side down on a glass slide. The slide is then examined under a microscope to identify the characteristic eggs (see Fig. 107-1B). As for other parasite infections, the collection of multiple samples has been reported to significantly improve diagnostic sensitivity.<sup>16</sup> Testing at night or first thing in the morning is reported to improve sensitivity. Eggs or adult parasites are rarely seen in fecal samples collected for diagnosis of other intestinal helminth infections such as ascariasis or whipworm or hookworm infections. Adult pinworms can sometimes be seen on the perianal skin (see Fig. 107-2) or in the anal canal during proctoscopy. Likewise, adult worms may occasionally be identified on toilet paper, diapers, or underwear. Infection does not generally result in eosinophilia; no serologic test is available.

## TREATMENT

Although several effective anthelmintics are available, the benzimidazole anthelmintic mebendazole is the most widely used drug showing useful efficacy. It is generally administered as a single dose of 100 mg, for which a cure rate in excess of 90% is expected.<sup>17</sup> Alternatives include the other widely used benzimidazole drug, albendazole, also as a single dose of 400 mg, and pyrantel pamoate as a single dose of 11 mg/kg (up to a maximum dose of 1.0 g). The more recently approved broad-spectrum anthelmintic ivermectin also shows useful activity, with a single oral dose ranging from 50 to 200 µg/kg resulting in a cure rate of 85%.<sup>18</sup> Older drugs that are now less widely available or used but still are effective include pyriminyl pamoate 5 mg/kg up to a maximal dose of 250 mg and piperazine in a dose of 65 mg/kg for 7 days. A second course of therapy should be readministered 1 to 2 weeks after the first dose to cover for auto- or reinfection. Likewise, all individuals sharing a household where the index case is a child should be given empiric treatment.

Infection in pregnancy poses a significant clinical dilemma, with some patients suffering great discomfort. Unfortunately, the safety in pregnancy of most agents has yet to be established, and some drugs have shown teratogenic effects in animal models when administered in high dose. However, in a number of retrospective surveys of women who took mebendazole in the first trimester of pregnancy, the rate of congenital abnormalities, fetal loss, or neonatal death has not been found to be significantly higher than in the general population.<sup>19,20</sup> In a large World Health Organization (WHO)-sponsored study of over 7000 Sri Lankan women who took

mebendazole during pregnancy a beneficial effect was observed overall, with a significantly lower rate of stillbirth and perinatal death observed in those who took the drug in comparison to those who did not, likely reflecting improved iron status due to cure of hookworm infection.<sup>21</sup> However, among those who took the drug contrary to advice during the first trimester there was a trend toward a higher incidence of major congenital defects, with a rate of 2.5% observed in those who took the drug versus 1.5% among those who did not (odds ratio of 1.66; 95% confidence interval, 0.81–3.56). Studies of single-dose albendazole therapy in pregnant women undertaken in Sierra Leone did not demonstrate any observed increase in frequency of fetal loss or malformation.<sup>22</sup> In a recent review of 49 cases of albendazole administration to women in the first trimester of pregnancy, no cases of congenital abnormalities were reported.<sup>23</sup> In the two cases studied where neonatal death ensued, the deaths were not likely attributable to the albendazole exposure. Nonetheless, prudence should be observed in the administration of these drugs to pregnant or potentially pregnant women, especially in the first trimester of pregnancy.

## PREVENTION AND CONTROL

As mentioned previously, reinfection in household and institutional environments is common, and repeated group treatment, usually with single-dose mebendazole, is advised. Other advisable measures include careful attention to hand hygiene, trimming of fingernails, and washing of bedclothes and underwear. Regular vacuuming of house dust has also been advised, despite the lack of evidence supporting a significant role of fomites in transmission. Little is known about host immunity, and vaccine development has not been pursued. Among intestinal helminths, this parasite has not assumed a large place in public health programs in developed or developing countries.

# Trichuriasis

EDWARD S. COOPER

## INTRODUCTION

Members of *Trichuris* species are successful nematode parasites of mammalian bowel and *Trichuris trichiura* has had much opportunity to coevolve with man. The *T. Trichuris* species itself is a parasite of both Old World and New World monkeys and apes.<sup>1</sup> Its human presence is associated with poor hygiene rather than a specifically tropical environment, although warmth and moisture in the soil enhance transmission through promotion of the viability of the infective stages. Until about 30 years ago, four things led to the underestimation of *T. trichiura* as a pathogen.

1. Low-intensity infections, which are by far the most common, are asymptomatic.
2. *Trichuris* is seldom found as the only pathogen, but is commonly just one of multiple health and environmental threats.
3. The onset of significant symptoms is often too slow to alarm the family.
4. It produces a transient, although prolonged, disease of the developing child while seldom causing disability to adults.

However, severe infections of children are amenable to treatment with highly effective drugs with minimal side effects; and this makes case-detection and treatment most rewarding and population-based prevention most productive. In the last decade, there has been a steady increase in reports on all aspects of trichuriasis, with publications reported by Medline now approaching 40 per year.

## AGENT

*Trichuris trichiura* is a member of the nematode superfamily Trichuroidea and is related to *Trichinella spiralis*. The genus was previously often called *Trichocephalus*, logically enough since the hairlike part (tricho-) is in fact the head end (cephalus). However, the original name given by Linnaeus (1771), in the mistaken belief that the hairlike part was the tail (uris), is the official name. Whipworm is a commonly used unofficial name. The adult is shaped like a whip, with the handle representing the wider posterior section containing the reproductive organs and the intestine, while the long, fine anterior part, called the stichosome, contains the long pharynx. The whole is about 4 cm long. The male has a curled posterior end. The eggs are thick-walled and barrel-shaped, about 50 µm long, with a plug at each pole.

Eggs, passed in the feces, contain a zygote and are not infective until embryonation, which takes place in the soil over 2 to 4 weeks. The egg now contains the L1 larva. Following human ingestion, the larva is released in the stomach and passes into the intestine. It penetrates the epithelium in the mucosal crypts of the cecum.<sup>2</sup> The larva develops by molting, and the adult develops from the L4 stage, by now having migrated with the epithelial cells up the sides of the crypts. The anterior part of the adult lies in a tunnel within the epithelium between the mouths of the crypts, while the posterior part is free in the lumen. The stichosome is surrounded by a syncytium and debris of the epithelium. Each female produces up to 20,000 eggs per day; the life expectancy of a worm within the host has been estimated at 1 to 3 years,<sup>2</sup> which would imply that some adults live far longer.

## EPIDEMIOLOGY AND ECOLOGY

Up to a quarter of humanity carries *T. trichiura* as an intestinal parasite. An estimate for the number of Chinese infected (212 million)<sup>3</sup> has brought the world estimate to over 1 billion infected human hosts. However, all parasitic infections have an aggregated ("clumped") distribution among their hosts. This is extreme in trichuriasis, where over 90% of a community may be infected but only 10% or fewer have intense, symptomatic infections.<sup>4</sup> There is as yet no clear evidence on any factor making the intensely infected hosts especially susceptible, apart from the obvious one of environmental exposure related to hygienic practices. Familial aggregation occurs.<sup>5</sup> After treatment, there is a tendency for the most heavily infected to become the most heavily re-infected, but there is much crossing over between light and heavy strata too.<sup>6</sup> The role of domestic pigs in transmission is unknown, although passage of the life cycle through the pig is possible.<sup>7</sup> Warm, damp soil provides the best medium for transmission once it is fecally contaminated. *T. trichiura* is found in humid, tropical environments but also in temperate climates including Northern Europe and South Africa. Although transmission occurs in cool climates, hyperendemicity is correlated with higher temperatures and lower altitudes.<sup>8</sup> The nematode is the predominant intestinal parasite in many communities in Africa and the Americas.

## DISEASE

Most infections are asymptomatic. In heavy infections (many adult worms, see next section), stools become loose and frequent and there is tenesmus. Frequency can exceed 12 stools per 24 hours and nocturnal stooling is especially characteristic. Stools consist largely of mucus but may also be watery. There is a characteristic acrid smell. Frank blood is common. Trichuriasis is one of the most frequently identified causes of recurrent rectal prolapse and the worms may be seen on the prolapsed mucosa. Children with this degree of symptomatic infection are almost invariably severely anemic and growth-retarded.<sup>9</sup> They are also geophagic and much of their stool may consist of ingested earth or even small stones. Finger-clubbing is common, correlated in prevalence and severity with the number of adult worms harbored.<sup>10</sup>

# Whipworm (*Trichuris trichiura*)

## PATHOGENESIS AND IMMUNITY

Light infections (20 adult worms or fewer) are not associated with any discernible morbidity. Heavy infections (200 adult worms or more) are associated consistently with the clear-cut syndrome described previously, which has both colonic and systemic features. The difference is not only one of parasite biomass (in which a 10-fold increase may scarcely be significant clinically), but perhaps more importantly of the site affected: In light infections, the worms are confined to the cecum and the ascending colon, whereas in heavy infections there are adult worms in the distal colon and rectum, and also often in the terminal ileum. The mucosa at these latter sites may have a greater tendency to a local hypersensitivity reaction to *T. trichiura*.

In the inflamed areas, especially the rectum, the mucosa is edematous. At the cellular level, the most significant

abnormalities are distended goblet cells, an increased concentration of superficial mast cells, which are degranulating, and an increase in the lamina propria of calprotectin-secreting cells, presumed to be monocytes.<sup>11</sup> Increased tumor necrosis factor (TNF)- $\alpha$  is both produced by lamina propria cells and found circulating in the peripheral blood.<sup>11,12</sup> Bloody mucus commonly exudes from the mucosal surface.

The systemic consequences are anemia and impaired growth.<sup>13</sup> The former is presumed to follow from direct loss from the gut of red blood cells followed by iron deficiency. The mechanism for the impaired growth is not clear but could involve both substrate-limited and substrate-wasting pathways. In support of the former is the finding of protein-losing enteropathy proportional to the worm burden,<sup>13</sup> and of the latter increased circulating TNF- $\alpha$ , which may inhibit appetite as well as having direct effects on cell division

and metabolism. Plasma insulin-like growth factor-I (IGF-I) concentration is found to be correspondingly reduced during the *Trichuris* dysentery syndrome (TDS), although it returns to a similar level to that of comparable children from the same community within a month of worm expulsion.<sup>14</sup> The increase in plasma IGF-I after treatment accompanies a fall in plasma TNF- $\alpha$ , an increase in collagen synthesis as shown by rising plasma pro-collagen type 1, and an acceleration in physical growth. Although it had been suggested that the beneficial effect of mebendazole on child growth might be due to some systemic effect other than through worm expulsion, a quite specific worm effect has now been shown.<sup>15</sup>

The elevation of acute phase proteins<sup>16</sup> is further evidence of a systemic component in the response to heavy *Trichuris* infection. Plasma viscosity<sup>16</sup> is also moderately elevated and declines slowly over a period of months, despite the rapid resolution of symptoms after anthelmintic treatment.

Concentrations of immunoglobulin A (IgA), IgM, and IgG antibody to *T. trichiura* are correlated with the host's current worm burden.<sup>17,18</sup> Specific responses of IgG1, IgG4, IgA, and IgE have been shown.<sup>12</sup> As with *Ascaris*, multiple reinfections with *Trichuris* are to be expected,<sup>19</sup> implying that protective immunity must be incomplete. Epidemiological data combined with serology can be interpreted as consistent with an increase in immunity with age, and as suggesting that both IgA<sup>17</sup> and IgE<sup>12</sup> may be mediators of this. Some genetic polymorphism in susceptibility<sup>20,21</sup> has been shown but, if this is so, it is all the more remarkable that prevalence of infection can approach 100% in large and diverse communities.<sup>22</sup> Evidence has been sought in humans<sup>12,23</sup> for the divergence in immune response seen in mice,<sup>24,25</sup> where a Th1 cytokine response has been associated with chronic infection and a Th2 response with parasite expulsion. The human responses have been diverse and inconsistent.<sup>12</sup>

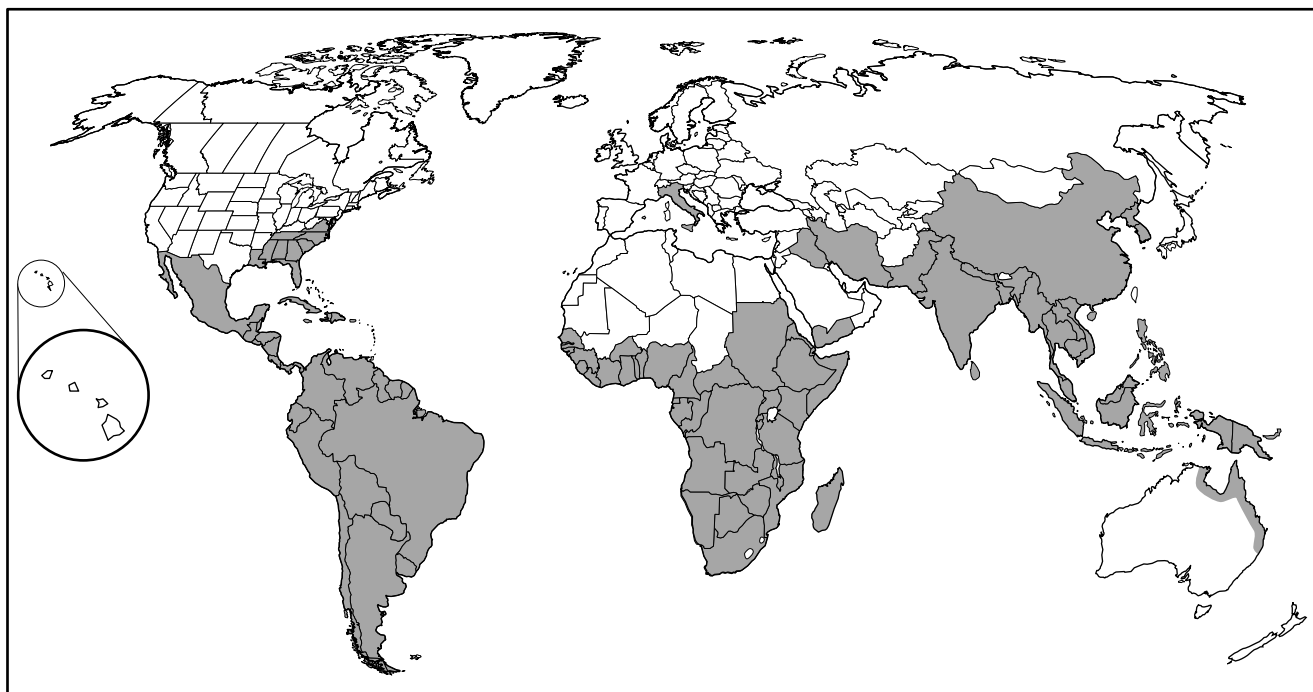

The most striking evidence for the converse, that chronic infection induces a Th2 response that inhibits the Th1 response, has come from the remarkable experiment of deliberately infecting patients suffering from Crohn's disease or ulcerative colitis with *T. suis* eggs as anti-Th1, and therefore anti-inflammatory, therapy. Preliminary results have been encouraging.<sup>26</sup>

Cytokine expression in human colonic mucosa biopsied as part of investigation of *Trichuris* dysentery syndrome suggests that both interferon- $\gamma$  (Th1) and interleukin-4 (Th2) may be strongly expressed in the mucosa of children with heavy and chronic infections with *T. trichiura*. This corresponds with recent data from peripheral blood.<sup>27</sup> It excludes T-cell anergy as an explanation for these exceptionally intense infections. In humans, downstream of T-cell recognition, some component of the immune response that leads to worm expulsion in mice appears to be either missing or attenuated.<sup>23</sup> Eosinophilia is often associated with trichuriasis, but its lack by no means excludes the diagnosis in any individual.

There may be neuropsychological effects of intense trichuriasis, manifest by impaired cognitive function<sup>28</sup> and especially locomotor development.<sup>29</sup> These effects are too subtle to present as a clear part of the clinical picture, unless the child is already suffering from severe social deprivation or cognitive disorder and so is more likely to have geophagia leading to the secondary acquisition of this heavy worm burden. The systemic inflammation, especially increased circulating TNF- $\alpha$ , is a possible mediator between the parasitized intestine and impairment of higher brain function.

## DIAGNOSIS

The differential diagnosis is from other causes of infective dysentery or idiopathic colitis. A stool specimen may be

*Trichuris trichiura*

examined by any of the techniques for parasites, but the Kato-Katz preparation is recommended for simplicity, reliability, and quantification. Although from a population perspective a count of eggs per gram (epg) of feces is well correlated with adult worm burden, this cannot be applied to the individual. With less than 1000 epg clinically significant trichuriasis is unlikely and with over 10,000 epg it is likely, but severe cases occur with absent eggs on a single stool specimen and some lightly infected children have over 10,000 epg. Proctoscopy showing worms on the rectal mucosa is more reliable evidence of *Trichuris colitis*,<sup>29</sup> and this can be used in the clinic. Colonoscopy sometimes reveals an intense colonic infection, either in a research setting or if the diagnosis has not been made before the procedure. It cannot be justified as a diagnostic procedure: Presumptive treatment or a trial of treatment is fully justified in a busy clinic setting.

## TREATMENT AND PROGNOSIS

Many anthelmintics effective against *Ascaris* fail against *Trichuris*, and to these must now be added ivermectin.<sup>30,31</sup> Mebendazole (Janssen's Vermox or generic) or albendazole (Zentel, Smith-Kline-Beecham) by mouth are effective and recommended. Single doses (mebendazole 100 mg to 500 mg; albendazole 400 mg) give a good chance of cure in light infections and are worthwhile in mass campaigns, but increasing probability of complete worm expulsion is a function of increasing exposure to the drug. For clinically significant infections, mebendazole 200 mg per day on 3 successive days is recommended, or albendazole 400 mg per day for 3 days. These drugs are contraindicated in pregnancy and not recommended for infants, but clinical judgment must be used in the event of symptomatic infection. Worm expulsion will be followed by clinical cure, but if the environment is unchanged re-infection is likely and re-treatment every 3 months,<sup>19</sup> or at least every year,<sup>32</sup> is well justified.

## PREVENTION AND CONTROL

Satisfactory fecal disposal using water-seal toilets or good pit-latrines completely interrupts the life cycle of these geohelminths. Hand washing and washing of any vegetables grown in fecally contaminated soil is also useful. In the real-life situation of crowded, poor dwellings, scarce piped water and heavily contaminated soil, mass chemotherapy with cyclical repetition is highly effective.<sup>32</sup> The children of preschool and school age should be targeted.<sup>2</sup> In regions where periodic mass treatments are being used to control lymphatic filariasis, single-dose treatments with albendazole together with ivermectin have proven more efficacious in diminishing *Trichuris* infections than single-dose treatments with albendazole alone or with albendazole combined with diethylcarbamazine.<sup>33,34</sup>

## INTRODUCTION

*Ascaris lumbricoides*, one of four species of nematodes that are soil-transmitted helminths, is among the most prevalent of parasitic infections in humans.<sup>1,2</sup> About a fifth of the world's population is estimated to be infected. *Ascaris* infections in people living in developed countries may also be due to *A. suum*, which is commonly found in domestic swine reared under conditions of poor hygiene. Taxonomists have yet to agree as to whether *A. lumbricoides* and *A. suum* are separate species.<sup>2</sup> However, identification to the generic level is all that clinicians require for case management and treatment. The high prevalence and diverse geographic spread of *A. lumbricoides* can be attributed to a number of factors, including the properties of its eggs in a variety of environmental conditions, the high number of eggs produced per female worm, and poor socio-economic conditions that facilitate spread of the organism. *Ascaris* persists wherever fecal sanitation is inadequate or lacking; indiscriminate defecation by infected people contaminates the social environment and guarantees transmission. Two separate populations of *A. lumbricoides* exist: (1) juvenile and adult worms that live predominantly within the human intestine, and (2) eggs that contaminate the environment. Infection is usually transmitted via ingestion of eggs from contaminated foodstuffs, although in regions with extremely high egg burdens, infection may occasionally occur via inhalation of eggs and swallowing infected respiratory secretions. Many infections are asymptomatic, but *Ascaris* infections can be causes of morbidity by contributing in endemic areas to impaired growth and development and of morbidity and mortality due to complications caused by adult worms. While the complication rate of *Ascaris* infection is low, the high worldwide prevalence of infections makes the overall number of complications (primarily intestinal obstruction) from *Ascaris* infection fairly high, with mortality from ascariasis perhaps as high as 10,000 to 100,000 deaths per year.<sup>3-5</sup>

## AGENT

*A. lumbricoides* is a nematode that has been recognized as a pathogen since ancient times, in part because of its extremely large size. Scientific description of the anatomy and clinical manifestations of *A. lumbricoides* was published by Tyson in 1683.<sup>6</sup> The female roundworm can reach lengths of

up to 400 mm (Fig. 109-1) and the male roundworm up to 350 mm, with diameters of 30 mm to 60 mm and a yellow-white or pinkish-grey color. Female worms produce up to 200,000 eggs per day while living in the human host for about a year; these eggs are passed in feces.<sup>2</sup> Eggs are oval in shape, measure approximately 60  $\mu$ m to 70  $\mu$ m in length, and are a yellow-brown color (Fig. 109-2). Fertilized eggs tend to be shorter and wider than unfertilized eggs.

One of the factors accounting for the high prevalence of *Ascaris* infections is the ability of eggs to survive for long periods in the right climate, even under a variety of environmental conditions. The egg shell has several layers that are protective against environmental factors. The outside of the egg is coated with a sticky layer of mucopolysaccharide, which facilitates adherence to fruit, vegetables, fingers, door knobs, and so on. Fertilized eggs contain embryos that require moisture, warmth, oxygen, and shade if they are to develop to the juvenile worm infective to humans. UV light disrupts this developmental process (embryonation), the rate of which is temperature-dependent.<sup>2,7</sup>

Once eggs are passed in the stool, they may take 2 to 4 weeks to fully embryonate and become infective. After these eggs are ingested by a human, infective juveniles escape from their egg shells in the small intestines of susceptible hosts. They penetrate the intestinal wall and migrate to the liver via the hepatic portal system. After about 4 days in the liver, survivors move on to the lungs, where they remain for 10 more days before moving up the trachea to be swallowed and so to become established in the small intestine where they live for up to a year.<sup>8</sup> Egg release by mature, inseminated female worms is estimated to begin about 70 days after the ingestion of infective eggs.<sup>2</sup> Fluoroscopic studies have revealed that the jejunum is the worms' optimum site but they may be found elsewhere in the small bowel and stomach, sometimes in the

biliary system, and more rarely in a variety of sites unconnected with the gastrointestinal tract.<sup>3,9</sup>

## EPIDEMIOLOGY

Geographic prevalence and distribution of *A. lumbricoides* are influenced largely by climate, sanitation provision and practices, literacy rates, socioeconomic conditions, cultural habits, and the availability of, and access to, health care. A number of epidemiologic studies of *Ascaris* have demonstrated its widespread worldwide distribution.<sup>10,11</sup>

Insight into the population biology and transmission dynamics can be understood by reference to a mathematical framework summarized by Anderson and May.<sup>12</sup> This work

demonstrated that host-parasite relationships between humans and *Ascaris* depend on the intensity of infection or worm burden per person. Worm burden explains the severity of disease, the success or otherwise of transmission, and the persistence of the infection in various groups in the community. Prevalence data account for the extent of *Ascaris* in a region while intensity data indicate the health risks for individuals and populations.

Modes of transmission of *A. lumbricoides* vary according to the type of community under examination. In a closed community, for example, within a small village or a family, infection is largely endemic and eggs are unlikely transferred from the outside. In a more open community, from either a rural or an urban locale, eggs can be transferred out of the community via sewage or contaminated soil but can be reintroduced into the community via contaminated produce. Finally, in a community formed under social conditions, for example, a school, factory, or some other closely knit social group, transmission will also occur.<sup>13</sup> *A. lumbricoides* infection has been believed to occur more in rural than in urban areas. However, as urbanization increases in many developing countries, so does the urbanization of *A. lumbricoides* increase. In general, children are infected more frequently than adults, perhaps reflecting increased soil contact from play and poorer hygiene. On the other hand, protective immunity may be weaker in children than adults.<sup>2</sup> Interestingly, *Ascaris* is regularly demonstrated to occur in familial clusters.<sup>14</sup>

Socioeconomic factors, particularly sanitation, play a large role in determining the degree of contamination of the human environment with fertile eggs. The prevalence of infection is increased where poor sanitation occurs and where the population is heavily involved with subsistence agriculture, particularly if raw human feces are used as fertilizer. High illiteracy

*Ascaris lumbricoides*

# *Ascaris lumbricoides*

\* Stool exam is often negative at this early stage

rates and particular cultural habits, such as using "night soil" (human excrement) as fertilizer and children playing in unsanitized soil, enhance transmission. Certain soils are more suited to egg survival.

Climate has a large influence on the pattern of *A. lumbricoides* infection in a particular region, in terms of the severity and character of symptoms as well as the seasonal pattern of disease. For example, in Africa, prevalence is higher in countries with warm, wet climates than in those with more arid climates.<sup>15,16</sup> A national study of *A. lumbricoides* infections in schoolchildren in Cameroon surveyed 22,000 children from 512 schools from various climatic zones and found a marked variability in prevalence rates, with low rates (5%) in the northern tropical zones, which were described as having a short rainy season and a long dry season, and rates up to 70% in the southern equatorial zones, characterized by abundant rainfall with few brief dry periods.<sup>17</sup> There were no differences within individual climatic zones in prevalence rates between

rural and urban populations or between low- and high-altitude regions.<sup>17</sup> In Saudi Arabia, where the pattern of transmission is seasonal, pulmonary symptoms from migrating *Ascaris* predominate over intestinal symptoms and occur from March to May, after the rainy season optimizes conditions for embryonation.<sup>18</sup>

Numerous studies have been done on the prevalence of *Ascaris* infection in a variety of populations and locales. In China, surveys have indicated that 531 million people are infected with *Ascaris* (47% prevalence rate) compared with 212 million and 194 million infected, respectively, with *Trichuris* and hookworm.<sup>19</sup> A study of schoolchildren in Lagos State, Nigeria, found that in 810 fecal samples, 74% demonstrated *A. lumbricoides*, with a mean egg load of 2544 eggs per gram (epg) of stool.<sup>20</sup> This high prevalence was associated with customs of indiscriminate defecation, eating contaminated produce, and poor hand washing.<sup>20</sup> In a village in rural Burma (now Myanmar), 77% of 783 people examined were infected with *Ascaris*, with age-specific prevalences that

reached a maximum of 92% from 5 to 9 years of age and a minimum of 65% from 50 years and older.<sup>21</sup> In an epidemiologic study of intestinal nematodes in children in the Ranomafana rain forest in southeastern Madagascar, examination of stool samples from 1292 children from birth to 10 years of age demonstrated a prevalence of *Ascaris* infection of 78%, with a prevalence of 34% by 6 to 12 months of age and 100% by 10 years of age.<sup>22</sup> As judged from fecal egg excretion densities (epg), the intensity of *Ascaris* infections, like those with *Trichuris trichiura*, typically are greatest in the early years of life, peaking at about 10 years of age and then declining.<sup>23</sup> This contrasts with hookworm infections, in which intensities do not peak until 20 to 25 years of age.<sup>23</sup> The greater intensities of *Ascaris* infections in young children make them at greatest risk for the clinical effects of *Ascaris* infections.

## CLINICAL MANIFESTATIONS

Most infections with *A. lumbricoides* are asymptomatic.<sup>3-5</sup> The spectrum of symptomatic disease from ascariasis is broad, ranging from mild abdominal discomfort to mild pulmonary symptoms to abdominal catastrophes resulting in death. Particular symptoms reflect the migration of larvae or adult worms in the involved organ system, and the intensity of symptoms generally relates to the worm burden of each host. Thus, children, who usually have the highest intensity of infection, tend to have more severe clinical presentations. The most common clinical syndromes of ascariasis are pneumonitis, intestinal obstruction, biliary obstruction, and pancreatic obstruction.<sup>2,24</sup> The most widespread manifestation of ascariasis is its adverse effect on the growth, development, and nutritional status of children.<sup>25,26</sup> Other rarer consequences of *Ascaris* infection, such as the presence of the worms in the brain, kidney, and placenta, have also been reported.<sup>2</sup>

The migration of developing larvae through the lungs are responsible for the pulmonary manifestations of *Ascaris* infections; and hence lung involvement is due to new infections acquired via eggs ingested in the antecedent weeks and not due to any established intrainestinal adult worms. Clinical syndromes result from both the physical disruption elicited by larvae as they cross from blood vessels into the airways and immune-mediated hypersensitivity reactions to the presence of larvae. *Ascaris* antigens are allergenic and there is conflicting data about their role as a cause of asthma.<sup>27-30</sup> Symptoms range from mild cough, with no radiologic changes, to a Löffler's syndrome with transient pulmonary infiltrates, dyspnea, severe cough, and eosinophilia (see Chapter 125). The severity of symptoms is a reflection of the larval burden. Given the life cycle of *A. lumbricoides*, stool samples may be negative until 2 to 3 months after the pulmonary symptoms occur, unless the patient was already harboring a patent infection. In countries where transmission of *Ascaris* is seasonal (e.g., Saudi Arabia), seasonal outbreaks of pneumonitis are typical,<sup>18</sup> while in countries with continuous transmission pulmonary disease is uncommon.

The large adult worms can elicit the intestinal symptoms of ascariasis. These may be referable to small bowel obstruction due to a large bolus of worms or to the migration of one or a few worms from their usual intraluminal locales. Symptoms relating to the presence of worms in the small intestine tend to be nonspecific and include generalized abdominal pain,

dyspepsia, appetite changes, or occasionally vomiting or diarrhea. The range of potentially serious intestinal manifestations of ascariasis is evident in series from a number of centers worldwide. For instance, in a review of abdominal ascariasis in children in Cape Town from 1958 to 1974, 528 presentations of acute abdominal symptoms were recorded, with a peak incidence in children from 4 to 8 years of age. In this series, 66% of the cases were intestinal obstruction, 25% were biliary obstruction, and 5% were pancreatitis.<sup>31</sup> In a review of 500 patients from India with hepatobiliary and pancreatic disease from *A. lumbricoides*, 274 patients presented with duodenal ascariasis, 171 with biliary ascariasis, 40 with hepatic ascariasis, 8 with gallbladder ascariasis, and 7 with pancreatic ascariasis.<sup>32</sup> The most common clinical presentation was that of biliary colic; patients presenting with acute cholangitis were the second most common.<sup>32</sup>

Intestinal obstruction can occur from a bolus of worms in the lumen of the intestine (Fig. 109-3). Children are at greater risk than adults, perhaps because of the smaller diameters of their intestines and their potential for greater worm burdens.<sup>24</sup> The numbers of worms needed to cause obstruction have been estimated to be greater than 60, with worm burdens being about 10-fold higher in fatal cases.<sup>33</sup> Complications of

**FIGURE 109-3** A bolus of worms causing intestinal obstruction. (From Zaman V: Atlas of Medical Parasitology, 2nd ed. Australia, ADIS Health Science Press, 1984.)

intestinal obstruction include bowel perforation with bacterial peritonitis due to seeding with gut bacterial flora as well as granulomatous peritonitis due to seeding with adult *Ascaris* worms and eggs.<sup>34</sup>

Biliary obstruction results from the presence of a worm or worms that have entered the biliary tree, where the flow of bile may be impaired, where spasms of the sphincter of Oddi may occur, or where stone formation may result.<sup>35</sup> Adult worms may migrate into the gallbladder,<sup>36</sup> sometimes becoming evident only after cholecystectomy.<sup>37</sup> Worms may also ascend the biliary tree to cause hepatic abscesses.<sup>38</sup> Pancreatitis, which occurs less frequently than biliary disease during ascariasis, can have a variety of clinical manifestations, ranging from abdominal pain and elevated serum amylase, to pancreatic calcifications, pseudocysts, or death.<sup>39</sup> As with intestinal obstruction, worms may be passed in stool or vomitus.

*Ascaris* infection affects the nutritional status of developing children and has been shown by some authors to directly decrease protein utilization, fat absorption, and increase lactose intolerance and vitamin A deficiency.<sup>25,26,40,41</sup> Not all authors have demonstrated a direct correlation between specific nutritional deficiencies and ascariasis.<sup>42–44</sup> There is agreement that *Ascaris* infection may contribute to or exacerbate poor nutritional status when there is a large worm burden present in persons who live in regions with other causes of malnutrition, such as other parasitic infections, poverty, poor living conditions, and poor diet. Careful studies have demonstrated improvement in growth and development in children treated for ascariasis.<sup>45,46</sup>

## **PATHOGENESIS AND IMMUNITY**

The pathology of *A. lumbricoides* infection is related to the human host response to the presence of larvae, eggs, or adult worms in a specific tissue or organ lumen. When the larvae migrate in human tissues, cells undergo mechanical trauma as well as lysis caused by larval enzymes. In various tissues, invading larvae can induce granuloma formation from surrounding eosinophils, neutrophils, and macrophages. Particularly, the presence of *A. lumbricoides* larvae in pulmonary parenchyma induces a hypersensitivity reaction that includes increased mucus production in the bronchi, peribronchial inflammation, and bronchial spasm.<sup>11</sup> Human infections with *Ascaris* lead to the development of immune responses polarized to the production of Th2 cytokines.<sup>47</sup>

The pathophysiologic consequences of *A. lumbricoides* in the gastrointestinal tract result from the physical presence of worms in the lumen of the small intestine or wherever worms may migrate. Although, in general, the intensity of symptoms is proportional to the worm burden, in an individual, a single worm may cause significant morbidity by migrating into a particular sphincter or duct and producing an obstructive clinical syndrome. For example, a single worm that migrates into the common bile duct can produce biliary obstruction. There is controversy as to whether production of antibodies to *A. lumbricoides* is protective or merely indicative of prior or current infection. Serology is rarely needed to diagnose *Ascaris* infection and is used more frequently in epidemiologic studies of ascariasis and of host responses to various intensities of infection. *Ascaris* infection produces both specific and nonspecific increases in circulating immunoglobulin E (IgE).

Studies have examined what protective role antibodies induced by *A. lumbricoides* may have in relation to re-infection. A case-control study of Bangladeshi children with different intensities of infection suggested that antibody response to infection mirrors intensity of infection and may have no protective role.<sup>48</sup> However, another study that examined total and *A. lumbricoides*-specific IgE levels in serum of children with documented infection with *A. lumbricoides*, who were treated and became re-infected multiple times, found that while subjects with high pretreatment total IgE levels had higher re-infection rates, subjects with higher pretreatment anti-*A. lumbricoides* IgE levels had lower re-infection rates. The authors suggested that specific IgE antibody may be protective against *A. lumbricoides* infection and that polyclonal stimulation of IgE may reduce the effectiveness of this protective response.<sup>49</sup>

## **DIAGNOSIS**

The parasitological diagnosis of *Ascaris* infection in the intestine is usually made by examining stool samples for eggs. A common method of examining a stool sample is the direct method, which involves mixing a small stool sample with a drop of 0.85% NaCl and examining the mixture on a slide under a microscope. Alternatively, much experience indicates that the Kato Katz method is the best available system. This method consists of 50 mg of fresh stool pressed under cellophane into a thin film on a slide, and then identifying and counting the eggs by microscopy. Other less commonly used techniques include the lactophenol cotton blue stain for wet mount stool preparation<sup>50</sup> and the Merthiolate Iodine Formalin (MIF) fecal technique.<sup>51</sup> Egg counts (epg) can measure both intensity of infection in an individual and prevalence of infection in a community.<sup>3</sup> The major deficiency of using egg counts to diagnose ascariasis or to measure intensity or prevalence of ascariasis is that it will miss infection with all male, all female, or juvenile worms. The other method of measuring intensity and prevalence of infection, although it is not generally used as a diagnostic tool, is to count the number of worms passed after anthelmintic chemotherapy.

A clinical diagnosis of *Ascaris* pneumonia is made in a patient with a recent potential exposure to infectious *Ascaris* eggs who presents with dyspnea, dry cough, fever, and eosinophilia. Examination of chest radiographs usually reveals fleeting pulmonary infiltrates and examination of the sputum may reveal Charcot-Leyden crystals (see Chapter 125). Because of the life cycle of *A. lumbricoides*, stool samples for eggs may be negative at the time of the clinical presentation of pneumonia.

Intestinal or biliary obstruction from *A. lumbricoides* should be considered in the appropriate clinical setting in someone from an *Ascaris* endemic region. Increasingly, radiographic and especially ultrasonographic techniques have been used with success to diagnose intestinal and biliary ascariasis. In intestinal ascariasis, ultrasound has reliably detected diagnostic linear echogenic images of adult worms.<sup>52,53</sup> In intra- and extra-hepatic biliary ascariasis, ultrasonography has also proven sensitive in detecting worms in the liver, biliary tract, gallbladder, and pancreas.<sup>53,54</sup> Thus, when available, contemporary non-invasive ultrasound imaging can be a valuable adjunct in ascertaining whether adult *Ascaris* worms are underlying intestinal or hepatopancreatobiliary tract clinical presentations.

With the administration of oral contrast material, adult ascarid worms can be visualized by CT scans and upper GI series as tubular filling defects at times with a thread of contrast material within their own intestinal tracts.<sup>55,56</sup>

## TREATMENT

The decisions to treat patients with ascariasis rest on several conditions, including a consideration of the potential of individuals to become readily reinfected and the resources available. In patients with uncomplicated intestinal ascariasis who reside in areas in which they are not likely to be reinfected, anthelmintic therapy is very much indicated to prevent any of the potentially serious consequences attributable to intestinal obstruction or the complications of biliary ascariasis. In regions where sanitation is poor, reinfections are likely. Thus, therapy needs to be balanced between the benefits of preventing later complications and potentially improving growth and development and any limitations on the availability of medical resources. In regions where lymphatic filariasis is present, ongoing mass treatment campaigns using periodic administrations of albendazole with ivermectin or diethylcarbamazine (see Chapter 98) can also help diminish the prevalence and intensity of *Ascaris* infections.<sup>57</sup>

The mainstays of drug therapy for the treatment of gastrointestinal ascariasis are the benzimidazoles (mebendazole and albendazole), levamisole, and pyrantel.<sup>58,59</sup> Benzimidazoles impair phosphorylation and glucose uptake in the parasite. Mebendazole and albendazole have been compared in differing doses and formulations<sup>60,61</sup> and for *Ascaris* infection are equally effective and well tolerated. Studies using single-dose regimens (300–500 mg of mebendazole or 400 mg of albendazole) have produced cure rates of 100%, although mebendazole may also be given as 100 mg twice a day for 3 days.<sup>58</sup> Informal consultations have concluded that WHO-recommended anthelmintic drugs<sup>59</sup> of proven quality may be given in appropriate doses to pregnant women, adolescent girls, women of reproductive age, and children aged at least 12 months, despite pregnancy Category B status. The members of the consultations advised that anthelmintic treatment should be avoided if possible during the first trimester of a pregnancy. Details covering all aspects of this matter including pharmacokinetics, safety, toxicology, and embryo toxicity are available in a series of reports.<sup>62–65</sup> None of the advice contradicts or undermines the judgments a physician must make on a case-by-case basis.

Pulmonary manifestations of recent *Ascaris* infections are self-limited and are not generally treated, except for supportive measures. It is unknown if anthelmintic therapy would be effective against lung-stage larvae and whether any larval death might heighten pulmonary inflammation. Although there are no published data to support this, it seems reasonable to screen carefully for gastrointestinal *A. lumbricoides* infection following pulmonary disease and to treat if evidence of *A. lumbricoides* is found in order to eradicate *A. lumbricoides* from the host.

While surgical interventions have conventionally been employed to treat the complications of intestinal ascariasis, with the heightened ability of ultrasonography to diagnose and localize adult *Ascaris* worms, increasingly there have been greater applications of nonsurgical approaches. In intestinal obstructions, medical management with anthelmintics can

be successful. In one series from India, 68 patients who presented with intestinal obstruction and no signs of peritonitis were successfully treated medically with anthelmintics and intravenous fluids, whereas 24 presenting with peritonitis required surgery and had a mortality of 50%.<sup>66</sup> Others likewise have reported series of intestinal obstructions successfully managed medically.<sup>67</sup>

For those with biliary tract complications of ascariasis, nonsurgical approaches are being successfully used. A report from Ecuador of 69 patients found that treatment with 800 mg albendazole orally and analgesics and antispasmodics obviated surgical intervention for all but one patient.<sup>68</sup> Duodenoscopy was done in 30 patients and extracted worms from the ampulla of Vater in 10 of these without a need for sphincterotomy. Thus, in 97% of their patients, *Ascaris* was treated successfully with medical therapy alone or with duodenoscopy.<sup>68</sup> Successful endoscopic approaches to the treatment of biliary ascariasis are increasingly being reported.<sup>69–72</sup>

## PREVENTION AND CONTROL

Prospects for the prevention of ascariasis will remain intractable in countries where *A. lumbricoides* infections are endemic until poverty is relieved, education and health awareness are strengthened, affordable and appropriate sanitation becomes widely available, and populations have access to essential drugs. Recently, good quality, generic versions of benzimidazoles have become available; one effective dose of a broad-spectrum anthelmintic drug such as albendazole is now priced at \$0.02.<sup>73</sup> This means that in areas endemic for ascariasis access to essential drugs<sup>59</sup> to control morbidity and relieve the burden of suffering can become a reality.<sup>63</sup> When anthelmintic chemotherapy is used on a community-wide basis, transmission is reduced because fewer eggs are released to contaminate the environment.<sup>74–77</sup> The problem of using the limited range of anthelmintic drugs is that drug resistance may emerge.<sup>63</sup> Accordingly, measures to control morbidity due to ascariasis will require careful planning based on the best available epidemiological information.<sup>12</sup> Ascariasis was once highly prevalent in Europe.<sup>6</sup> Its prevention was ensured when sanitation and sewage treatment systems were installed.

# Hookworm Infections

PETER J. HOTEZ

## INTRODUCTION

Hookworms are nematode endoparasites that cause intestinal blood loss during a part of their life cycle. An estimated 740 million people are infected with *Ancylostoma duodenale*, *Necator americanus*, or both.<sup>1</sup> *Necator americanus* is the predominant hookworm worldwide. Moderate and heavy worm burdens can result in hookworm disease, which is characterized by blood loss sufficient to produce iron deficiency and anemia in the human host. Children and women of reproductive age are particularly vulnerable to the effects of hookworm anemia.<sup>2,3</sup> For that reason, there is an increasing awareness of hookworm disease as a problem affecting maternal-child health.<sup>4</sup>

Perhaps more than any other nematode parasite, the life cycle of hookworms is intimately connected to rural poverty in warm climates. Hookworm infection is endemic in most developing areas of the subtropics and tropics where sanitation is poor and the environmental conditions, especially adequate moisture and sandy soils, support the survival and hatching of parasite eggs and then the subsequent migrations of larvae. Therefore, unlike *Ascaris* and *Trichuris* infections, hookworm is not usually a public health threat in urban slums. Instead, hookworm occurs primarily in impoverished tropical coastal communities and in areas of intense agricultural activity. In these high-transmission areas, hookworm infection remains endemic even when populations are routinely treated with anthelmintic drugs. In this setting, hookworm reinfection routinely occurs, and the prevalence and intensity of hookworm infection return to pretreatment levels within months.<sup>5</sup> Ultimately, the adequate control of hookworm may depend on new advances in biotechnology for the development of a first-generation hookworm vaccine.<sup>6</sup>

## AGENT

Hookworms are classically identified as adult nematode worms having a buccal capsule armed with teeth or cutting plates. The two major human parasitic species, *A. duodenale* and *N. americanus*, and the minor human zoonotic parasites, *Ancylostoma ceylanicum*, *Ancylostoma caninum*, and *Ancylostoma braziliense*, are members of the family Ancylostomatidae, superfamily Strongyloidea (Table 110-1). Although most clinicians usually consider the major species as generic "hookworms,"

there are, in fact, important differences between them<sup>7</sup> (Table 110-2). The clinical features of each hookworm infection are also distinct.<sup>8</sup>

*Necator americanus* ("American murderer") was probably discovered by Charles W. Stiles,<sup>9</sup> who identified the parasite as the principal cause of hookworm anemia in the rural southeastern United States. Many historians also credit Bailey K. Ashford of the U.S. Army Medical Corps, who encountered hyperendemic hookworm infection in Puerto Rico at the end of the Spanish-American War.<sup>10</sup> Adult *N. americanus* hookworms are relatively small compared to *A. duodenale*. The males are typically between 7 and 9 mm, and the females are between 9 and 11 mm in length. They live attached via cutting plates to the mucosa and submucosa of the small intestine, where they can live for 3 to 5 years. The blood loss caused by each *N. americanus* has been estimated by <sup>51</sup>Cr-labeled red blood cell measurements to be 0.01 to 0.04 mL per worm per day<sup>11</sup>; in general, it is much less than *A. duodenale*-associated blood loss. *Necator americanus* is therefore considered better adapted to human parasitism.<sup>7</sup> Each gravid female worm produces 5000 to 10,000 eggs per day, which exit from the host in feces. The eggs are thin-shelled, hyaline, and ovoid, measuring approximately 60 × 40 μm. Further development of the eggs depends on suitable external environmental conditions. These are usually met by adequate moisture and shade at temperatures of 20 to 30°C.<sup>12,13</sup> Egg hatching gives rise to a first-stage (L1) rhabditiform larva approximately 250 to 300 μm in length with a characteristic flask-shaped muscular esophagus. The L1 larva presumably feeds on bacteria and other organic debris prior to undergoing two spontaneous molts over the next week. Transformation to the infective third-stage larva (L3) is accompanied by a number of developmental changes, including elongation to a length of approximately 600 μm and cessation of feeding as a consequence of mouth closure and the buildup of an electron-dense "plug" in the buccal capsule. The infective larva is developmentally arrested and will remain so until it enters a suitable definitive host.<sup>14,15</sup> *Necator americanus* infects humans only through the skin. The L3 larvae increase their chances of finding a definitive host by a characteristic questing behavior. The infectious process of all hookworm larvae is intimately linked to the developmental biology of the parasite because host entry is accompanied by the resumption of hookworm larval development.<sup>15</sup> Developing L3 larvae enter into host venules and lymphatics, where they are swept into

Table 110-1 Human Hookworms

Hookworm	Animal Reservoir Host	Disease
<i>Necator americanus</i>	None	Anemia
<i>Ancylostoma duodenale</i>	None	Anemia
<i>Ancylostoma ceylanicum</i>	Dogs, cats	Enteritis
<i>Ancylostoma caninum</i>	Dogs	Eosinophilic enteritis
<i>Ancylostoma braziliense</i>	Dogs, cats	Cutaneous larval migrans
<i>Uncinaria stenocephala</i>	Dogs	Cutaneous larval migrans

Table 110-2    Properties of the Major Species of Hookworm

Property	<i>Ancylostoma duodenale</i>	<i>Necator americanus</i>
Size of adult (female slightly larger than male)	0.3–0.5 in.	0.2–0.4 in.
No. of eggs produced daily per worm	10,000–30,000	5000–10,000
Estimated amount of blood removed daily per worm	~0.2 mL (greater draw makes this species more virulent)	~0.02 mL
Mouthparts	Teeth	Cutting plates
Natural adult life span	1 yr	3–5 yr
Ability to produce infection if ingested	Yes	No
Ability of larvae to lie dormant	Yes	No

Data from Hoagland KE, Schad GA: *Necator americanus* and *Ancylostoma duodenale*: Life history parameters and epidemiological implications of two sympatric hookworms on humans. *Exp Parasitol* 44:36–49, 1978; and Hotez P: Human hookworm infection. In Farthing MJG, Keusch GT, Wakelin D (eds): *Enteric Infection 2: Intestinal Helminths*. London, Chapman & Hall, 1995, pp 129–150.

the pulmonary vasculature. The larvae migrate into the lungs and ascend the respiratory tree and epiglottis before entering the gastrointestinal tract. Entry into the small intestine stimulates the molting of L3 larvae to the L4 stage and then the adult stage. Approximately 49 to 56 days elapse from the time *N. americanus* L3 larvae enter the host until the adult female hookworm releases eggs.<sup>7,8</sup>

*Ancylostoma duodenale* was first identified from the intestine of an Italian woman in 1843 by Dubini. Its life cycle was largely elucidated by a series of impressive investigations in Egypt conducted by Looss.<sup>16</sup> The distinct features of the life cycle and life history stages of *A. duodenale* were a result of human investigations by G. A. Schad and colleagues working in rural West Bengal, India, in the late 1960s and early 1970s.<sup>7,13,17–23</sup> The adult *A. duodenale* is larger and more robust than *N. americanus*. Each adult male is 8 to 11 mm, whereas each adult female is 10 to 13 mm in length. Adult *A. duodenale* hookworms live only approximately 1 year in the small intestine. However, during that time they cause greater blood loss (0.05 to 0.30 mL per worm per day) and produce more eggs (10,000 to 30,000 eggs per day) than *N. americanus*.<sup>7,11</sup> Egg hatching of *A. duodenale* is faster than that of *N. americanus*.<sup>13</sup> *Ancylostoma duodenale* L3 larvae are infective via the oral route in addition to percutaneous entry.<sup>7,20</sup> In some endemic areas, oral ingestion of L3 larvae may be the predominant route of infection. Moreover, *A. duodenale* L3 larvae can remain in a developmentally arrested state, even after host entry.<sup>17,23</sup> Larval hypobiosis is considered evolutionarily adaptive because it allows the prolonged survival of the parasite in the host during times when the environment is unfavorable to larval development. For instance, *A. duodenale* L3 larvae probably remain arrested in the host during the hot and dry months of the year in some areas, only to resume development to egg-laying adult hookworms during or soon before the monsoon rains.<sup>17</sup> Arrested development may even explain how *A. duodenale* arrived with prehistoric humans during their early migrations into North America.<sup>24</sup> Arrested *A. duodenale* L3 larvae in maternal somatic tissues may also enter the mammary glands.<sup>23</sup> This phenomenon may account for vertical transmission of human ancylostomiasis to infants.<sup>2,23,25</sup>

Human intestinal infection with *A. ceylanicum* is probably a zoonosis transmitted by L3 larvae from eggs in either dog or cat feces and does not result in host blood loss and therefore is not considered clinically significant. However, zoonotic intestinal infection from the dog hookworm *A. caninum* can occasionally result in a severe eosinophilic enteritis syndrome.<sup>26–31</sup> Nonintestinal cutaneous larva migrans (CLM; “creeping eruption”) occurs when L3 larvae of the dog and cat hookworm *A. braziliense* enter the skin but subsequently abort the infection (see Chapter 103).

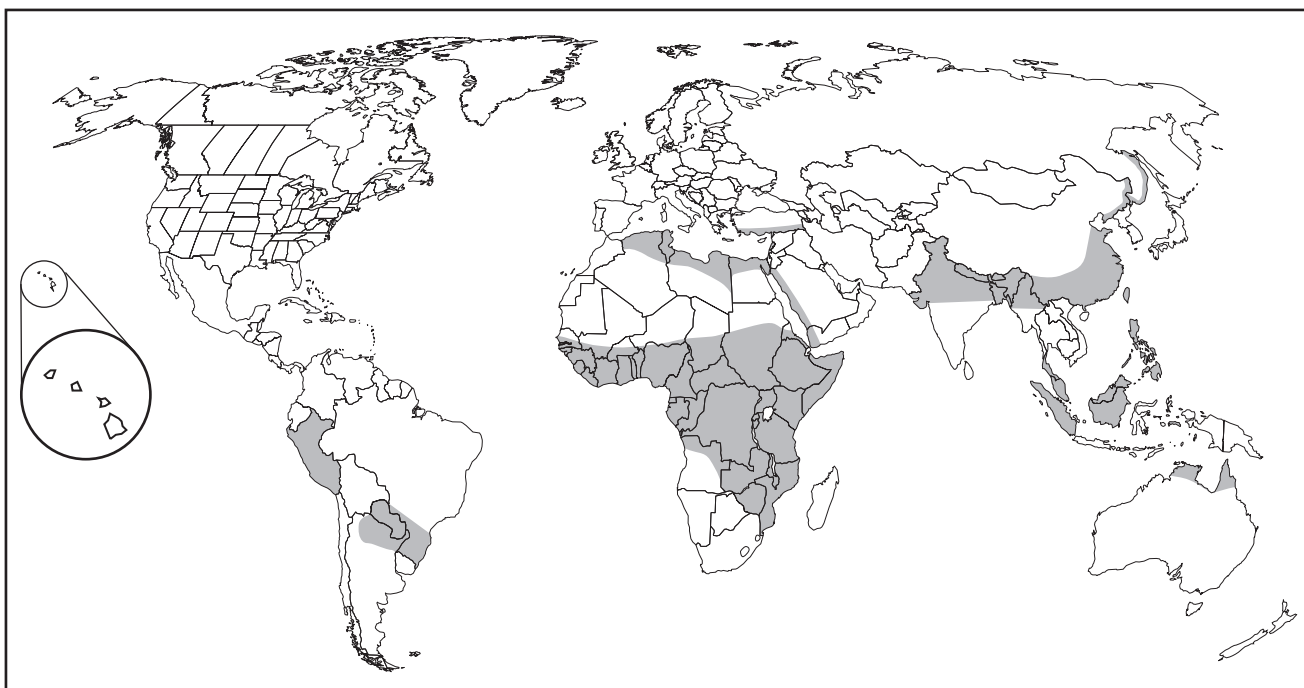

## EPIDEMIOLOGY

As noted in the Introduction, hookworm infections are common throughout the rural areas of the tropics and subtropics. Hookworm is intimately associated with the agrarian practices of societies in developing countries and is one of the most prevalent infections of humans. Coastal communities in the tropics typically have the highest intensity hookworm infections; presumably this observation reflects the mild humid climate and sandy soils in these regions, which are

favorable to transmission.<sup>32</sup> Overall, the highest prevalence and intensity of hookworm occur in sub-Saharan Africa, followed by China and Southeast Asia.<sup>1</sup> China boasts the most accurate prevalence estimates because of an unusual thorough nationwide survey in which fecal examinations were performed on 1,477,742 people.<sup>33</sup> An estimated 194 million Chinese (17% prevalence) are infected with hookworms. Whether hookworm infection in any given endemic area is due to *A. duodenale* or *N. americanus* is often unknown because differentiation between the two species is not routinely performed in the parasite diagnostic laboratory. Often, endemic hookworm is reported as either “ancylostomiasis” or “uncinariasis” (necatoriasis) when, in reality, no efforts were made to investigate the actual etiologic agent. Worldwide, *Necator* infections are more common than ancylostoma infections. However, when the worm burdens in a given community are similar, *A. duodenale* infections produce greater blood loss and endemic hookworm anemia than *N. americanus* infections.<sup>34</sup>

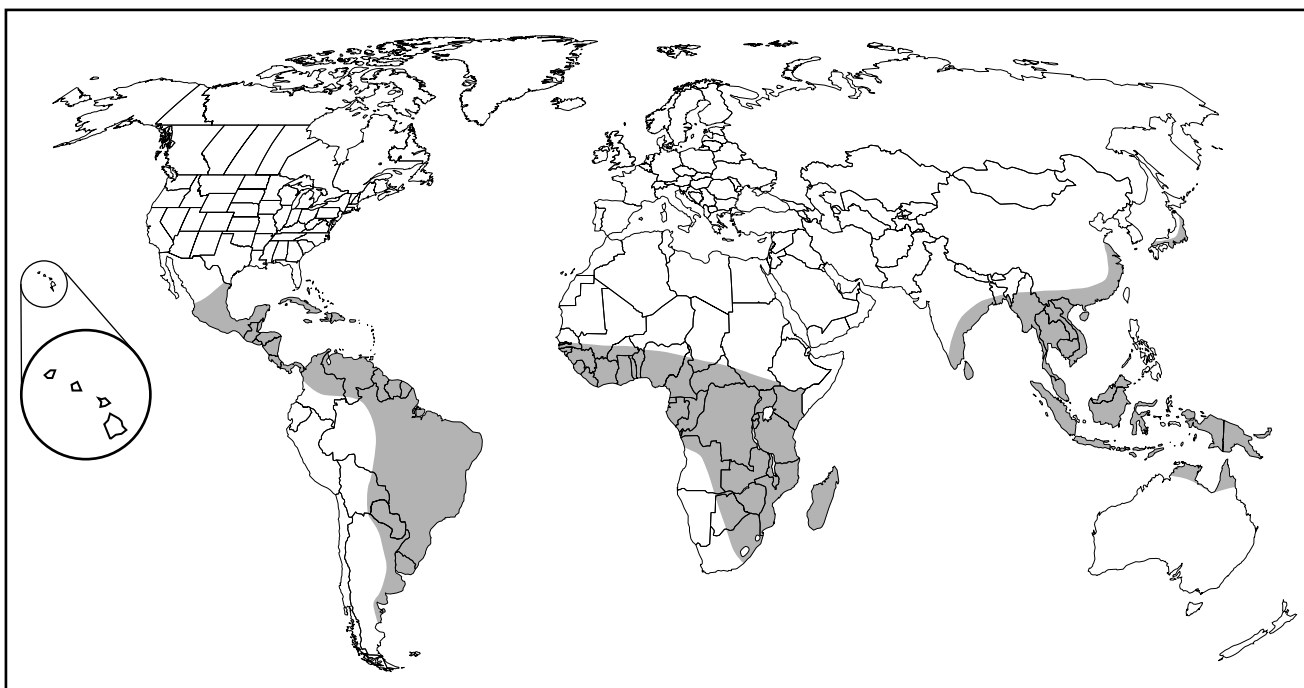

Infections with *N. americanus* are found predominantly between the tropics of Cancer and Capricorn. *N. americanus* is the predominant hookworm in Central and South America, hence the designation New World hookworm. *Necator* infections still occur in North America, especially in southern Mexico; rare pockets may even remain in the southeastern United States, although it is no longer a significant public health threat there. Hookworm was reported from rural Georgia in the early 1970s<sup>35</sup> and, more recently, from east Texas. *N. americanus* is the predominant hookworm of sub-Saharan Africa, southern China, southern India, and Southeast Asia. Infections with *A. duodenale* frequently overlap *N. americanus* infections in areas of Africa, India, and China. However, they also occur as either the exclusive or predominant hookworm of northern India and China and North Africa. Possibly, the ability of *A. duodenale* to undergo arrested development in the host allows the parasite to survive in climatic conditions that are unfavorable for *N. americanus*. Arrested development also accounts for the seasonality of ancylostomiasis. In rural West Bengal, India, and presumably elsewhere, the premonsoon rise in human fecal egg excretion occurs as a consequence of arrested hookworm larvae entering the intestine and developing into adult hookworms.<sup>17,23</sup> Some endemic ancylostomiasis still occurs in Brazil, Paraguay, northern Argentina, and Peru, although it is gradually being displaced by *Necator* infections.<sup>36</sup> *Ancylostoma ceylanicum* is a minor hookworm species of India and Southeast Asia.<sup>8</sup> *Ancylostoma caninum* has been identified as the cause of an emerging zoonotic eosinophilic enteritis syndrome in Australia.<sup>26–31</sup> Eosinophilic enteritis from *A. caninum* has been reported recently in Louisiana. CLM from *A. braziliense* is found in many areas of the tropics and subtropics, including the Gulf Coast, and southern regions of that Atlantic seaboard. It also occurs commonly in Caribbean tropical beach resorts and is thus a common problem seen in the travel medicine clinic.<sup>37</sup>

Hookworm infection is prevalent in almost all age classes in an endemic area. The characteristic pattern of age prevalence is one of an initial rise in childhood to a stable asymptote in early adulthood.<sup>2</sup> Rarely, because of infantile disease from vertical transmission, *A. duodenale* infections can also be found in children younger than 1 year of age.<sup>25</sup> Similar to other soil-transmitted helminths (STHs), hookworm exhibits

*Ancylostoma duodenale*

(In many regions, information on prevalence and speciation is limited.)

*Necator americanus*

(In many regions, information on prevalence and speciation is limited.)

an overdispersed distribution, with the majority (usually between 65% and 85%) of infected individuals in an endemic community exhibiting low-intensity infections, and a minority (usually between 15% and 35%) exhibiting moderate- and heavy-intensity infections. In contrast, there are marked differences in the age-dependent intensity patterns for hookworm compared with other STH infections.<sup>2</sup> Whereas worm burdens with *Ascaris* or *Trichuris* are often heaviest in children older than 2 years of age and then decline in adolescence, the worm burdens associated with hookworm infection do not exhibit such a clearcut pattern. It is not uncommon, for instance, for hookworm intensities to decline only slightly in adulthood or even to plateau or increase.<sup>2,38</sup> Studies from several different endemic areas suggest that humans are predisposed to acquire certain hookworm infection intensities so that people who are heavily infected prior to specific anthelmintic drug therapy will often reacquire heavy infections when left in the same environment.<sup>22</sup> Increasing evidence indicates a genetic basis for hookworm predisposition.

## DISEASE

Repeated percutaneous exposure to infective hookworm larvae of either *A. duodenale* or *N. americanus* results in a papulovesicular dermatitis sometimes referred to as “ground itch.” The pruritus and burning associated with ground itch typically are most intense at the site of host entry, usually on the hands and feet, and last less than 1 week. Some species of animal hookworms, including *A. braziliense*, will migrate laterally in the epidermis and give rise to local inflammation that follows the serpiginous migratory pathways of the larvae. This condition, CLM, presents commonly on the lower extremities or buttocks, usually within 2 weeks to several months after exposure to *A. braziliense* L3 larvae. Approximately 20% of patients with CLM will have eosinophilia, and some will develop pulmonary infiltrates (see Chapter 103).<sup>37</sup>

A second, urticarial rash can subsequently occur with the onset of *A. duodenale* or *N. americanus* larval migrations through the lungs. Hookworm pneumonitis occurs as the L3 larvae enter the alveoli and ascend the respiratory tree; it is commonly associated with wheezing, dyspnea, and a nonproductive cough. Hookworm pneumonitis is less severe than other verminous pneumonias caused by *Ascaris* or *Toxocara*. Eosinophilia can begin during the larval migratory phase, but it typically peaks when the L3 enter the small intestine. Oral ingestion of large numbers of *A. duodenale* L3 larvae results 1 or a few days later in a syndrome (Wakana disease) consisting of nausea, vomiting, cough, dyspnea, and eosinophilia.

Attachment and tissue invasion of adult *A. duodenale* and *N. americanus* hookworms to the intestinal mucosa and submucosa is accompanied by mild abdominal pain, nausea, and anorexia. The gastrointestinal symptoms are more pronounced in patients with eosinophilic enteritis from zoonotic *A. caninum* infection. Intestinal parasitism by hookworms begins approximately 1.5 to 3 months after host entry by the L3 larvae. The prepatent period can last up to 1 year or possibly even longer if the L3 larvae of *A. duodenale* first undergo a period of arrested development.<sup>18</sup> Hookworm-associated blood loss results from the parasite-mediated destruction of capillaries in the intestinal mucosa. The degree of iron deficiency or anemia is dependent on a number of variables, including

(1) worm burden; (2) type of hookworm—*A. duodenale* causes more blood loss than *N. americanus*; (3) iron reserves and diet of the host; and (4) overall host nutritional status.<sup>8</sup> In very heavy infections, hookworm anemia will cause signs and symptoms of iron-deficiency anemia: fatigue, exertional dyspnea, poor concentration, koilonychia (spoon nail deformity), pale sclerae, and heart murmurs. In addition to presenting with profound iron deficiency, people with heavy hookworm burdens can develop protein malnutrition from chronic plasma protein loss and even the signs and symptoms of kwashiorkor.<sup>8</sup> Some of these patients will develop a pasty and sallow appearance, a condition known as chlorosis.<sup>39</sup> During pregnancy, the anemia resulting from hookworm disease has been linked to increased maternal mortality and several adverse neonatal outcomes, including low birth weight and increased morbidity and mortality.<sup>2,3</sup>

An extreme form of hookworm anemia, with high mortality, occurs in infants heavily infected with *A. duodenale*, who exhibit melena, diarrhea, pallor, and failure to thrive.<sup>25</sup> Most of the cases of infantile ancylostomiasis, which may result from vertical transmission of L3 via lactogenic transmission, have been reported from Asia.

Patients harboring light and moderate hookworm infections may also develop more subtle sequelae of iron deficiency. Of increasing interest is the effect of chronic moderate parasitism and iron deficiency on intellectual, cognitive, and physical growth of hookworm-infected children.<sup>40</sup>

## PATHOGENESIS AND IMMUNITY

Infective larval migrations through tissues usually do not cause severe visceral lesions, although heavy infections can result in hookworm pneumonitis.<sup>8</sup> However, the inflammation associated with skin entry is pronounced and is probably exacerbated by the release of eicosanoids and hydrolytic enzymes from migrating L3 larvae.<sup>41–44</sup> Hookworm larvae also release a family of proteins known as the *Ancylostoma*-secreted proteins (ASPs) of unknown function, which contain amino acid sequences homologous to plant proteins, insect venom allergens, and other members of the pathogenesis-related protein superfamily.<sup>6,45,46</sup> The ASPs include ASP-1, a 45-kDa protein, and ASP-2, a 22-kDa protein.<sup>45,46</sup> The ASPs are released in vitro in response to a low-molecular-weight factor found in serum as well as glutathione and glutathione derivatives.<sup>15</sup> Continuous release requires the presence of the hostlike stimulus. It is believed that the parasites release the ASPs during the early stages of host entry. CLM occurs when *A. braziliense* L3 larvae fail to penetrate the basement membrane of the epidermal–dermal junction and migrate laterally in the skin.

Hookworm-induced blood loss occurs at the site of adult parasite intestinal attachment. Hookworms use their teeth (*A. duodenale*) or cutting plates (*N. americanus*) to fasten onto the mucosa and submucosa, where they secrete a battery of pharmacologically active polypeptides that prevent blood from clotting and downregulate the host inflammatory response.<sup>4,47–53</sup> Among the peptides identified, cloned and expressed from the adult dog hookworm *A. caninum* (but presumably also released by *A. duodenale*), are a family of serine protease inhibitors that inhibit clotting factor Xa and tissue factor VIIa.<sup>47,48</sup> Work is in progress to develop the hookworm anticoagulants as therapeutic agents for cardiovascular disease

as well as the disseminated intravascular coagulation that occurs during Ebola virus infection.<sup>54</sup> Another macromolecule released by adult hookworms is neutrophil inhibitory factor (NIF).<sup>55</sup> NIF binds to the A domain of the integrin Mac-1 (CD11b/CD18) and probably downregulates several types of invading leukocytes. Adult hookworms also release hydrolytic enzymes.<sup>56–59</sup> The destruction of mucosal capillaries and the resultant extravasation of anticoagulated blood account for hookworm-associated blood loss leading to iron-deficiency anemia. Some of the red blood cells are lysed and the released hemoglobin is degraded by an orchestrated cascade of hemoglobinas that line the hookworm gut.<sup>59,60</sup> Chronic iron deficiency is particularly detrimental in childhood and may directly impair cognitive and intellectual abilities by interfering with the development of dopaminergic neurons and the biosynthesis of brain enzymes with iron prosthetic groups.<sup>61–63</sup>

The human immune responses to hookworms are not well characterized. Immunoepidemiologic studies and observations with self-administered *N. americanus* infections suggest that humoral antibodies and cellular responses to hookworm antigens often are not linked to resistance to reinfection.<sup>64–66</sup> It has been hypothesized that hookworms are immunosuppressive and may promote susceptibility to other infections, including malaria and HIV/AIDS.<sup>2,67–69</sup> In the laboratory, however, immunity to canine hookworm infections has been produced by administering repeated doses of living larvae or larvae attenuated by ionizing radiation.<sup>70,71</sup> Hookworm immunity generated by living larval vaccines is not sterile but manifests by reduced worm burdens and decreased egg fecundity of the adult hookworms.<sup>71</sup> Evidence suggests that the protective effect offered by living larval hookworm vaccines may be reproduced by immunization with genetically engineered recombinant ASP polypeptides.<sup>6,72,73</sup>

## DIAGNOSIS

Severe hookworm anemia clinically resembles iron-deficiency anemia. The physical signs and symptoms have been outlined previously. A peripheral blood smear from a heavily infected patient will demonstrate the presence of microcytic hypochromic red blood cells. Measurement of hemoglobin concentration will also help to confirm the diagnosis. Eosinophilia is often a prominent feature of the complete blood count. In many endemic areas, other causes of anemia should be excluded, including malaria, HIV/AIDS, and hemoglobinopathies. Hookworm will also exacerbate anemia in patients with underlying nutritional deficiencies. Occasionally, a patient will be diagnosed early in the clinical course of hookworm infection because of a characteristic rash, pruritus, and pulmonary symptoms.

A definitive diagnosis of hookworm infection is established by identifying hookworm eggs from feces under light microscopy. Fecal concentration techniques are not required to diagnose moderate or heavy infections, or even most light infections. Quantitative egg counts are sometimes useful for determining the intensity of infection; this is essential to epidemiologic investigations since prevalence determination provides superficial information. Common quantitative techniques include the Kato–Katz, Beaver direct egg count, Stoll dilutional egg count, and McMaster techniques.<sup>74</sup> Hookworm eggs are easily differentiated from other common

human intestinal nematodes, such as *Ascaris* and *Trichuris*. However, the eggs of *A. duodenale* and *N. americanus* are not usually distinguishable by light microscopy. Species assignment of eggs using the polymerase chain reaction is under investigation.<sup>75</sup> Currently, however, species assignment usually requires either recovery of the adult worms from patients treated with an anthelmintic agent or rearing L3 larvae from eggs by fecal cultures.<sup>74</sup> It is cautioned, however, that the benzimidazole anthelmintic drugs frequently cause adult worm degeneration, making species assignment difficult. Characteristic features that distinguish *N. americanus* L3 larvae from *A. duodenale* include a prominent buccal spear and conspicuous transverse striations present on the sheath in the tail regions in the former. L3 larvae of *Strongyloides* have a characteristic notched tail not found in hookworm L3 larvae.

Human *A. caninum* infections that result in eosinophilic enteritis usually result in negative fecal examinations. Often, a single male or non gravid female adult hookworm living in an ectopic gastrointestinal site can cause eosinophilic enteritis. Therefore, definitive diagnosis may require identification of the parasite by either upper endoscopy or sigmoidoscopy. CLM is most often diagnosed clinically and must be differentiated from scabies.<sup>37</sup> Unlike patients with CLM, the mite *Sarcoptes scabiei* or its eggs can be demonstrated from skin scrapings. Patients with CLM may not have eosinophilia or a rise in IgE titer as they frequently do in systemic helminthic infections (see Chapter 103).<sup>37</sup>

## TREATMENT AND PROGNOSIS

The benzimidazole anthelmintic drugs, mebendazole and albendazole, are the current treatment of choice for removing adult hookworms from the gastrointestinal tract.<sup>76</sup> Both agents act on the microtubules of the parasite. Mebendazole is given either in a single 500-mg dose or 100 mg twice daily for 3 days; albendazole is given 400 mg once.<sup>76</sup> The benzimidazoles are teratogenic and embryotoxic in experimental animals and have not been rigorously tested in young children or in pregnancy. However, increasing experience with these agents given during mass chemotherapy programs in developing countries indicates that they are probably safe in children older than 1 year of age and therefore should be given to hookworm-infected preschool children, as well as pregnant women in their second and third trimesters.<sup>77,78</sup> In at least one anecdotal report from Papua New Guinea, thousands of children were treated with mebendazole and albendazole with no side effects.<sup>79</sup> Occasional adverse effects of the benzimidazoles include diarrhea, abdominal pain, and the induction of adult *Ascaris* worm migrations to ectopic sites.<sup>76</sup> Rarely, the benzimidazoles will cause leukopenia, alopecia, and an increase in serum transaminases.<sup>76</sup> As second-line agents, pyrantel pamoate, levamisole, bephenium hydroxynaphthoate, metrifonate, and even tetrachloroethylene must be used in developing countries. However, because albendazole and mebendazole are now available as low-cost generic medicines, these other agents are no longer commonly used.

The World Health Organization has advocated the use of single-dose albendazole or mebendazole for mass treatment programs of school-age children with STH infections.<sup>77</sup> Both agents will reduce hookworm burdens below the threshold that would otherwise result in disease. Mass treatment of school-age children offers a number of health- and

non-health-related benefits to children, including improvement in iron and hemoglobin status, physical growth, cognition, educational achievement, and school absenteeism.<sup>2,80</sup> However, in areas of intense transmission, hookworm-infected children can be expected to reacquire their infections to pretreatment levels approximately 4 to 12 months after receiving albendazole or mebendazole.<sup>5</sup> In addition, one study noted diminishing efficacy of mebendazole with repeated use, possibly because of emerging anthelmintic drug resistance.<sup>81,82</sup> There is also no direct evidence that benzimidazole will eradicate populations of arrested, hypobiotic larvae in human tissues. Therefore, patients with latent *A. duodenale* infections could theoretically have positive fecal examinations months after curative treatment, even in non-endemic areas. The prognosis of hookworm infection is dependent on its chronicity, its intensity, and the iron reserves and diet of the host. Many of the sequelae of hookworm anemia are potentially reversible with anthelmintic drugs and iron supplementation.<sup>83,84</sup> However, severe hookworm iron-deficiency anemia in infancy may cause irreversible effects.<sup>61</sup> The majority of patients with CLM are cured by oral administration of albendazole (400 mg daily for 3 days) or ivermectin (200 µg per kg daily for 1 or 2 days).

## PREVENTION AND CONTROL

Since there are no animal reservoir hosts for *A. duodenale* or *N. americanus*, effective sanitation should interrupt hookworm transmission and prevent reinfection. However, by itself, the effect of sanitation in terms of reducing community hookworm prevalence and intensity is often not realized for decades.<sup>2,85</sup> Economic development with improvement in living standards and the introduction of piped water supplies, water-borne sewage systems, mechanized agriculture, and replacement of human feces with chemical fertilizers will control endemic hookworm and are largely responsible for the control of hookworm infection in North America, Europe, Japan, and Korea. Presumably, these measures would be effective in many developing countries. Health education to advise on the proper use of sanitation facilities and to avoid using uncomposted human manure is also an essential component of control.<sup>86</sup>

Because of the health and educational benefits of albendazole and mebendazole outlined previously, and because they have become available as low-cost generic drugs, there has been interest in using them to control STH infections worldwide. At the World Health Assembly in 2001, a resolution was put forward (resolution 54.19) urging endemic countries to control STH infections and regularly treat at least 75% of all at-risk school-age children with albendazole or mebendazole (as well as praziquantel in schistosomiasis endemic regions) by 2010 ([www.who.int/wormcontrol](http://www.who.int/wormcontrol)).<sup>77,80</sup> It has been further proposed that, wherever possible, the schools provide the infrastructure for anthelmintic health care delivery, with trained teachers responsible for administering the drugs.<sup>77</sup> Because *Ascaris*, *Trichuris*, and *Schistosoma* worm burdens are highest among school-age children, there is optimism that implementation of resolution 54.19 will have a significant impact on these infections and possibly help to reduce transmission. However, because hookworm disease burdens are frequently concentrated among adult populations (including pregnant women), and preschool children are vulnerable to

permanent intellectual and cognitive deficits from iron deficiency,<sup>61</sup> there is concern that such school-based programs could fail to effectively target vulnerable hookworm-infected populations.<sup>6,80</sup> School-based deworming will also not reduce hookworm transmission. Moreover, where high-intensity endemic hookworm occurs, reinfection will occur within months necessitating, in some cases, thrice yearly treatments.<sup>80–82</sup> There is further concern that such frequent administration of benzimidazoles may promote the emergence of drug resistance.<sup>80–82</sup> For these reasons, there is great interest in developing new tools and strategies to control hookworm infection in developing countries. A first-generation recombinant vaccine for human necator infection has been developed and is scheduled for phase 1 clinical trials.<sup>2,6,80</sup>

# Strongyloidiasis

AFZAL A. SIDDIQUI  
ROBERT M. GENTA  
STEVEN L. BERK

## INTRODUCTION

Strongyloidiasis is caused by *Strongyloides stercoralis*. It is the fourth most important intestinal nematode infection in the world. Although isolated pockets of low endemicity and indigenous sporadic infections have often been found in many temperate areas of the world, *S. stercoralis* infection predominantly occurs in humid tropical areas. The specific impact of chronic infection with *S. stercoralis* on human health is difficult to evaluate in populations with widespread enteric diseases, parasitoses, and malnutrition. However, strongyloidiasis is not generally believed to be one of the major causes of morbidity worldwide. Infection of humans with *S. stercoralis* usually produces an asymptomatic chronic disease of the gastrointestinal tract that can remain undetected for several decades. However, in immunocompromised patients and especially those receiving corticosteroids, hyperinfection can develop with the dissemination of larvae to extraintestinal organs and can result in mortality rates as high as 85%.

## AGENT

### History

In the second half of the 19th century, French troops deployed in the then French colony of Cochinchina (modern Vietnam) often developed a persistent severe diarrhea that became known among military personnel as “diarrhée de la Cochinchine.” In 1876 Louis Normand, a physician stationed at the Toulon Naval Hospital, discovered small worms in the stools of some of the repatriated soldiers and reported his findings to the Academy of Sciences of Paris.<sup>1</sup> Bavay, a colleague of Normand, named the worm *Anguillula stercoralis* (from the Latin words for “small eel” and “dung”) and later provided a detailed description of the worm under the new name, *Anguillula intestinalis*. Several parasitologists became interested in the new nematode, and in 1879 Grassi established a new genus which he called *Strongyloides* (Greek *strongylos*, “round”) and gave *Strongyloides stercoralis* its current name.<sup>2</sup> In subsequent years, the cycle was partially described, but the important issues of the free-living cycle, parthenogenesis, and the autoinfectious cycle were not fully elucidated until the experimental work of Fülleborn (1911), Kreis (1932), and Faust (1933). Although several detailed

descriptions of individuals infected with *S. stercoralis* were published in the early part of this century,<sup>3</sup> it was not until Napier<sup>4</sup> conducted extensive clinical surveys of repatriated British soldiers and Galliard<sup>5,6</sup> performed systematic experiments in normal and immunosuppressed dogs that the clinical importance of strongyloidiasis began to be fully appreciated.

## Taxonomy

The family Strongylidae (class Secernentasia, order Rhabdiorida) comprises only the genus *Strongyloides*. The members of this genus, also called threadworms, are heterogenetic, with free-living and parasitic generations, and include at least 40 named species.<sup>7</sup> Most of these are parasites of mammals, but some can be found in birds, reptiles, and amphibians. The only species discussed here is *S. stercoralis*. *Strongyloides fuelleborni* is a parasite of primates that may also infect humans. Several other species are also important, either because they can cause disease in livestock (*Strongyloides ransomi*, *Strongyloides westeri*, *Strongyloides papillosus*) or because they can be used as models of human strongyloidiasis (*Strongyloides ratti*).<sup>8</sup>

## Life Cycle and Morphology

The infection is acquired when filariform larvae (slender, fast-moving worms measuring approximately 50  $\mu\text{m}$  in diameter and between 350 and 600  $\mu\text{m}$  in length) penetrate the skin of a susceptible host, enter a venous or lymphatic channel, and are transported to the lungs. Here they break out of the capillaries into the alveoli (Fig. 111-1), migrate to the trachea as they mature, and are eventually swallowed. Parasitic females lodge in the lamina propria of the duodenum and the proximal jejunum, where they lay eggs (Fig. 111-2). From the hatching eggs emerge rhabditiform larvae. These shorter and slower worms (approximately 60  $\mu\text{m}$  in diameter and 250 to 300  $\mu\text{m}$  in length) migrate into the intestinal lumen and eventually pass with the feces into the external environment. There, depending on poorly understood environmental conditions, the rhabditiform larvae may either directly molt into infective (parasitic) filariform larvae able to repenetrates the skin of a suitable host or switch to a free-living cycle. In this latter, indirect (or heterogonic) cycle, four ecdyses

**FIGURE 111-1** Fragment of a *Strongyloides stercoralis* filariform larva in the alveolar spaces of an immunocompetent host. There are scattered blood cells but no significant hemorrhage.

**FIGURE 111-2** A and B, Section of an adult *Strongyloides stercoralis* female worm and embryonate eggs in the lamina propria of an immunocompetent subject. There is moderate mononuclear inflammation in the vicinity of the parasites.

(molts) lead to the development of adult male and female worms (Fig. 111-3). These mate and produce a generation of offspring whose filariform stage will have the ability to reenter parasitic life.<sup>8</sup> The characteristic of *S. stercoralis* that sets it apart from all other major human parasitic worms is that a small portion of the rhabditiform larvae molt within the host's intestine into the filariform stage. These tissue-penetrating infective larvae may penetrate the colonic wall (Fig. 111-4) or the perianal skin, complete an internal cycle, and become established as mature adult females in the small intestine.

**FIGURE 111-3** Filariform larva (approximately 550 µm in length) and an immature adult worm (1.3 mm) recovered from the feces of an immunocompromised dog experimentally infected with *Strongyloides stercoralis*. It is extremely rare to recover from the stools of immunocompetent patients any *S. stercoralis* stages other than the shorter (approximately 300 µm) and plumper rhabditiform larvae (right upper corner inset).

This process, known as autoinfection, is believed to represent the mechanism by which *S. stercoralis* can persist virtually indefinitely in infected hosts.<sup>9,10</sup>

## EPIDEMIOLOGY

The information regarding the worldwide prevalence of strongyloidiasis is inconsistent, with estimates varying between 3 million and 100 million people infected worldwide.<sup>11</sup> The unreliability of these estimates is further reflected in the wide range of reported prevalence rates, which vary between less than 1% and 85% in populations living in adjacent regions of the same country.<sup>12,13</sup> Given these limitations, *S. stercoralis* probably is present in virtually all tropical and subtropical regions of the world.<sup>14</sup> Areas of low endemicity (less than 1% to 3%) still exist in several countries of Europe (e.g., northern Italy, France, Spain, Switzerland, Poland), the United States (e.g., Appalachian region<sup>15</sup> and West Virginia<sup>16</sup>), Japan (Okinawa), and Australia (aboriginal populations).<sup>14</sup> In some areas, for example, the Valencian

**FIGURE 111-4** Intestinal muscularis mucosae and submucosa with a full-length section of a penetrating filariform larva.

# *Strongyloides stercoralis*

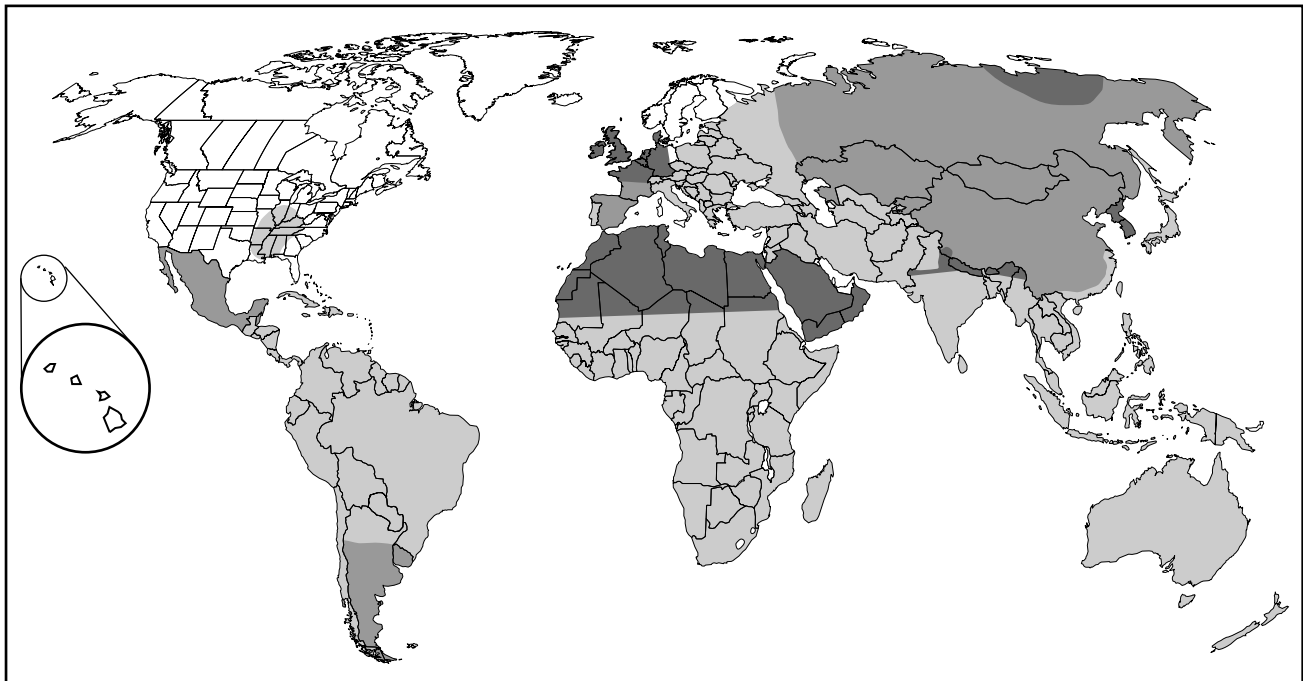

community in Spain, the high prevalence of strongyloidiasis has been attributed to the agricultural activities.<sup>17</sup> Strongyloidiasis has also been found intermittently in institutionalized individuals<sup>18</sup> as well as in patients of cancer centers<sup>19</sup> in several North American locations where the parasite is not endemic in the general population. The accompanying map depicts the estimated prevalence of strongyloidiasis in the world. Considering the long persistence of *S. stercoralis* in its host and its relatively high prevalence in some tropical and subtropical populations, physicians practicing in industrialized countries should consider strongyloidiasis in immigrant or refugee patients born in developing regions<sup>20</sup> as well as in persons from known local areas of endemicity.

## PATHOGENESIS AND IMMUNITY

Chronic strongyloidiasis is probably sustained by a relatively low and stable number of adult worms that reside in harmony within their host's intestine and survive by means of

well-regulated autoinfection.<sup>21</sup> Autoinfection is believed to be regulated by host cell-mediated immunity.<sup>9,22,23</sup> When immunosuppression impairs this regulatory function, increasing numbers of autoinfective larvae complete the cycle, and the population of parasitic adult worms increases (hyperinfection). Eventually, the extraordinary numbers of migrating larvae deviate from the canonical route (intestine → venous bed → lungs → trachea → intestine) and disseminate to other organs, including meningeal spaces and brain, liver, kidneys, lymph nodes, and cutaneous and subcutaneous tissues, where they cause hemorrhage and inflammation and implant gram-negative bacteria carried from fecal material. The resulting syndrome, known as disseminated strongyloidiasis, is nearly always fatal.<sup>9,23</sup>

The validity of the preceding model has been questioned by Schad and colleagues<sup>24</sup> and other investigators,<sup>25,26</sup> who used an experimental canine model of disseminated strongyloidiasis to show that only a few larvae could be recovered from the lungs of dogs with massive hyperinfection.

### *Strongyloides stercoralis*

- Known endemicity
- Unknown endemicity but probably present
- Unknown endemicity but probably absent

Later, in a series of experiments based on the compartmental analysis of radiolabeled larvae and mathematical modeling, they presented convincing evidence that the tracheobronchial route in the dog was not used by the majority of the migrating larvae.<sup>27,28</sup> According to their model, larvae that began their migration in the skin (primary infection) or in the distal ileum (autoinfection) were not more likely to pass through the lungs than through any other organ, suggesting that the migratory pathway involved random dissemination throughout the body. However, this conclusion may not be applicable to the cycle in humans, since large numbers of larvae are frequently identified in bronchoalveolar lavage fluid from hyperinfected patients.<sup>29,30</sup>

Recently, the authors have challenged the accepted paradigm that host mechanisms regulate hyperinfection and dissemination.<sup>14,21</sup> The theory that host immunity alone controls infection fails to consider the role that parasites may play in their own regulation. The adverse impact of increased parasite density on egg production and growth has been demonstrated for several intestinal helminths. Although distinguishing between host resistance and direct parasite-to-parasite effects may be difficult, it seems clear that most parasites reach a particular population size or a critical biomass, after which yet unknown regulatory mechanisms intervene to limit the population.<sup>28</sup>

The authors propose that *S. stercoralis* may have the ability to reach an optimal population size in the human small intestine. If the initial infective dose of larvae is low, a higher rate of intraluminal molting (i.e., autoinfection) occurs until the "optimal" size of the adult population is reached.

If *S. stercoralis*, like other nematodes, transmits its molting signal by molting hormones (ecdysteroids),<sup>31</sup> adult females adjust their production of ecdysteroids to levels sufficient to replace the dying adults. During the initial phase of infection, the host mounts an immune response directed at all tissue stages of the parasite.<sup>22,32–35</sup> These responses may not eradicate all parasites but may limit the size of the parasite population. Impaired immune responses may allow the growth of larger numbers of parasites, as reported in agammaglobulinemic patients,<sup>36</sup> human T-cell lymphotropic virus type I (HTLV-I)-infected subjects,<sup>37</sup> and severely malnourished children,<sup>38</sup> but total dysregulation of the parasite population does not seem to occur, since worms, in part, regulate their own growth.

The level of ecdysteroid-like substances is generally negligible in healthy subjects.<sup>31</sup> The administration of exogenous or endogenous corticosteroids may result in increased amounts of ecdysteroid-like substances in the host's tissues, including the intestinal wall, where adult females reside. These substances may act as molting signals for the eggs or rhabditiform larvae, which transform intraluminally into excessive numbers of filariform larvae. Available data are not sufficient to prove a dose-dependent effect, but it is indeed remarkable that patients who develop fulminating hyperinfection after only a few days of steroid administration are usually those who have received intravenous methylprednisone.<sup>39</sup> Once an intestinal population has become very large (e.g., 100,000 adult worms) it continues to expand rapidly, even at low molting rates, and the discontinuation of steroids is not sufficient to arrest the population growth, which leads to the host's death.

On the basis of recent observations, the authors further postulate that in *S. stercoralis* these developmental processes are regulated via a class of transcription factors that typically regulates genes in response to fat soluble hormones, such as steroids or fatty acids; as is the case for the free-living nematode *Caenorhabditis elegans*. We have recently described a gene in *S. stercoralis*<sup>40</sup> that showed significant homology with a number of nuclear hormone receptors including the dauer formation loci (*daf*) gene, *daf-12* of *C. elegans*, and ecdysone receptors of insects.<sup>40</sup> The identification of *daf-12* orthologs from *S. stercoralis* and from *Dirofilaria immitis* suggests that this component of the genetic pathway is conserved among nematodes. *Daf-12* regulates the dauer diapause and developmental age in *C. elegans*, and it is possible that mechanisms similar to those acting in *C. elegans* may also regulate the development in *S. stercoralis*. Furthermore, in an animal model of *S. stercoralis*, when normal male gerbils were infected subcutaneously with 1000 infective filariform larvae, the infected animals harbored moderate numbers ( $83.6 \pm 27.6$ ) of adult worms at 35 days after infection.<sup>41</sup> More interestingly, a low-grade infection persisted for 131 days, mimicking the chronic nature of human infections. Gerbils treated weekly with 2 mg of methylprednisolone acetate developed hyperinfective strongyloidiasis, with up to 8000 autoinfective larvae occurring in these animals at postinfection day 21. Autoinfection never occurred in normal (untreated) gerbils.<sup>41</sup> This animal study, coupled with examples from human case reports, reinforces our argument that immune suppression per se is not the major cause of hyperinfection but rather it is the direct effect of steroid on the parasite that causes the hyperinfection.

### Pathologic Changes

The pathologic lesions associated with chronic, uncomplicated *S. stercoralis* have received little attention, because only rarely have patients with such lesions come to autopsy. However, pathologic descriptions of the lesions in a few patients in whom strongyloidiasis was an incidental finding, our own experience, and animal studies<sup>25,42,43</sup> indicate that the worms can exist in the intestinal mucosa without causing significant inflammatory responses or tissue damage (see Fig. 111-1). The classic description of the pathologic changes in strongyloidiasis was made by De Paola and associates<sup>44</sup> in 1962 and later updated by Genta and Caymmi-Gomes.<sup>45</sup> When present, intestinal lesions range from mild mucosal congestion and abundant mucoid secretions ("catarrhal enteritis"), with a mildly increased mononuclear infiltrate in the lamina propria, to a more severe "edematous enteritis," with a grossly thickened intestinal wall. Submucosal edema, flattening of the villi, and parasites scattered throughout the lamina propria may be observed microscopically. The most severe form ("ulcerative enteritis") is almost exclusively seen in association with hyperinfection. The intestinal walls may be rigid owing to the edema and fibrosis resulting from long-standing inflammation, and the mucosa may show atrophy, erosions, and ulcerations. An abundant inflammatory infiltrate, most often consisting of neutrophils, as well as all stages of *S. stercoralis*, are present throughout the intestinal mucosa. Jejunal perforation has been reported in patients with the ulcerative enteritis form of strongyloidiasis.<sup>46</sup>

**FIGURE 111-5** Gastric mucosal biopsy with numerous fragments of *Strongyloides stercoralis* larvae in a patient with AIDS and multiple opportunistic infections. The larvae were present in the mucus but were not seen penetrating the gastric mucosa itself.

Uncommonly, the mucosal damage occurs predominantly in the large intestine, simulating ulcerative colitis and pseudopolypoidosis.<sup>47,48</sup> Recently, a form of eosinophilic colitis associated with strongyloidiasis has been described in older patients.<sup>49</sup> *S. stercoralis* larvae have been found in the appendix, and eosinophilic appendicitis apparently caused by this parasite has been reported.<sup>50,51</sup> In patients with disseminated strongyloidiasis, the intestinal lesions reflect the large number of worms dwelling within the small intestinal mucosa and penetrating the intestinal walls. In addition, the stomach<sup>52,53</sup> (Fig. 111-5) and peritoneal cavity<sup>50,54,55</sup> may be invaded by migrating parasites. However, because most of these patients are receiving immunosuppressive doses of corticosteroids, the inflammatory responses are often minimal in spite of extensive tissue damage.

Migrating parasites may cause mechanical damage as well as inflammation in other organs. As larvae penetrate the large intestine, they create small breaks in the mucosa that facilitate the invasion of the bloodstream by enteric bacteria. The larvae themselves carry bacteria on their cuticle to distant sites. In human patients, the extraintestinal organ most commonly affected by this migratory damage is the lung. In severe disseminated infection, when hundreds of thousands of adult parasites dwell in the intestine and millions of larvae migrate throughout the body, alveolar microhemorrhages may result in massive pulmonary bleeding<sup>56</sup> (Fig. 111-6). The widespread dissemination of larvae is almost invariably associated with polymicrobial sepsis, diffuse or patchy bronchopneumonia, pulmonary and cerebral abscesses, and meningitis.<sup>23</sup> Filariform larvae, and occasionally rhabditiform larvae and adult worms, also may disseminate to mesenteric lymph nodes and the biliary tract, as well as the liver, pancreas, spleen, heart, endocrine glands, and ovaries.<sup>45</sup> In these locations the parasite may induce a granulomatous response.<sup>57,58</sup>

### DISEASE

No other nematode has been associated with as broad a spectrum of manifestations or been implicated as the cause of so many different clinical syndromes as *S. stercoralis*.

**FIGURE 111-6** *Left*, severe intra-alveolar hemorrhage and fragment of a larva (arrow) in a patient with disseminated strongyloidiasis. In some patients, larvae may be found within the alveolar walls, where they may form granulomas. *Right*, A possible early granuloma around a fragment of larva (arrow).

The majority of persons with chronic infection are either asymptomatic or have mild, nonspecific symptoms. In contrast, disseminated strongyloidiasis is a catastrophic event that, if untreated, invariably results in death.

### Gastrointestinal Manifestations

Epigastric abdominal pain, postprandial fullness or bloating, and heartburn are among the symptoms most commonly reported, and brief episodes of diarrhea alternating with constipation may also occur.<sup>59,60</sup> Occult blood is occasionally detected in the stools of subjects with chronic infections,<sup>61</sup> and even massive colonic<sup>62</sup> and gastric hemorrhage<sup>63</sup> have been reported. Physical examination of chronically infected patients is normal or reveals only mild abdominal tenderness on palpation. Rarely, chronic strongyloidiasis may resemble inflammatory bowel disease, particularly ulcerative colitis, and the endoscopic appearance may be that of pseudopolyposis.<sup>47</sup> Although malabsorption has been reported frequently in patients with strongyloidiasis,<sup>64</sup> a clear causal relationship between *S. stercoralis* infection and malabsorption in otherwise healthy subjects has not been established.<sup>65</sup>

In contrast to the usually inconsequential nature of chronic strongyloidiasis, the gastrointestinal manifestations of disseminated strongyloidiasis are almost invariably serious. Hyperinfection is often heralded by profuse diarrhea, which is a consequence of the erosions, ulcerations, and edema caused by millions of adult worms and filariform larvae in the mucosa of the small and large intestine.<sup>23</sup> Malabsorption, exudation, and altered motility may also result. These mucosal changes predispose the patient to bacterial enterocolitis and, after variable periods of diarrhea, paralytic ileus.<sup>66</sup> Possibly because of the large numbers of larvae migrating from the large intestine into the circulation,<sup>67</sup> polymicrobial (predominantly gram-negative) sepsis may occur and local infections and abscesses may develop in virtually any organ.<sup>23,67</sup> Larvae have been detected in the liver, stomach, and pancreas of patients with overwhelming infections, but their presence in these locations is not known to be associated with characteristic symptoms.<sup>68</sup>

### Pulmonary Manifestations

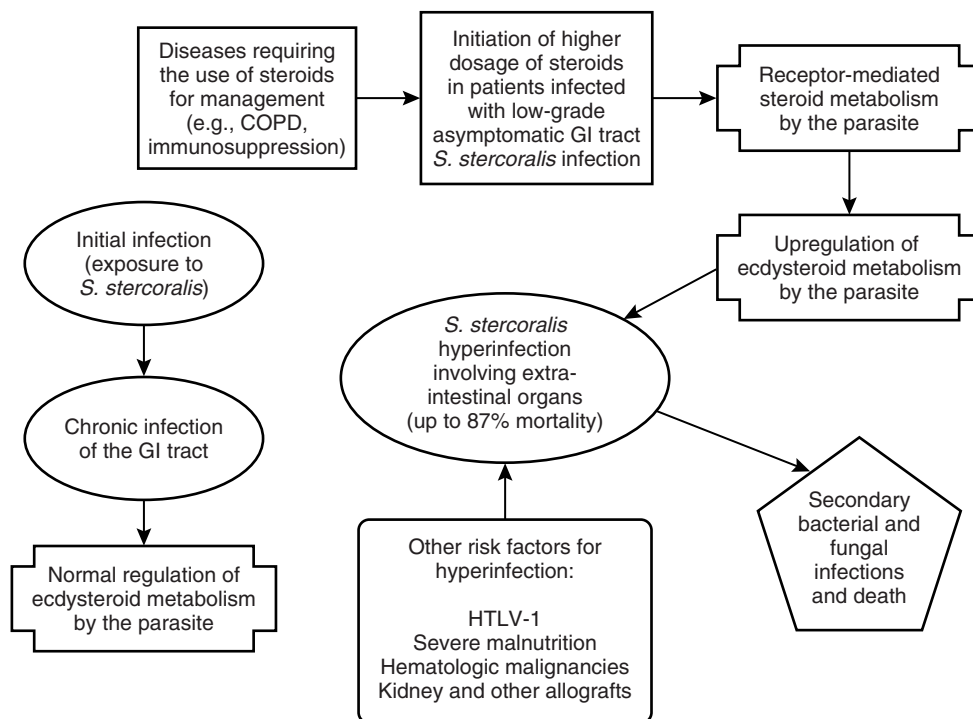

Although patients with chronic obstructive pulmonary disease may have an increased risk of strongyloidiasis,<sup>14</sup> no respiratory signs or symptoms are associated with chronic strongyloidiasis. In these infections, the numbers of larvae passing through the lungs are probably so small that they do not cause significant tissue damage.<sup>69</sup> However, patients who presented with asthma (most likely unrelated to the infection) and were treated with corticosteroids later developed disseminated strongyloidiasis.<sup>70,71</sup> In these situations, how hyperinfection can develop is illustrated in a conceptual model shown in Figure 111-7. In summary, in patients with disseminated strongyloidiasis, pulmonary manifestations are the rule, particularly diffuse bronchopneumonia. Intra-alveolar hemorrhage, often so severe as to cause the patient's death, is frequent. Filariform larvae and at times rhabditiform larvae and even eggs may be present in respiratory secretions in those with disseminated strongyloidiasis.

### Neurologic Manifestations

Uncomplicated strongyloidiasis is not associated with neurologic manifestations. Gram-negative polymicrobial meningitis is the most frequent central nervous system manifestation of disseminated strongyloidiasis, and in some cases, larvae have been identified in the cerebrospinal fluid<sup>72</sup> (Fig. 111-8). Less common is the formation of cerebral and cerebellar abscesses containing *S. stercoralis* larvae.<sup>73</sup>

### Cutaneous Manifestations

Two types of cutaneous manifestations have been described in patients with chronic strongyloidiasis: urticarial rashes, possibly caused by a sensitization to parasite antigens, and a characteristic, migratory serpiginous dermatitis caused by the subcutaneous migration of filariform larvae (larva currens). The latter has been reported more often in Caucasian patients infected in the Far East.<sup>74–76</sup> Some patients with disseminated infection, leukopenia, and various degrees of thrombocytopenia may develop generalized or periumbilical

**FIGURE 111-7** Conceptual model of the development of *Strongyloides stercoralis* in patients receiving corticosteroids for treatment of diseases such as chronic obstructive pulmonary disease.

cutaneous purpura,<sup>77–80</sup> probably related to the rupture of small vessels caused by filariform larvae migrating in the dermis.<sup>76,79</sup>

### Other Systemic Manifestations

Arthritis is an unusual manifestation of strongyloidiasis and is associated with the local deposition of immunocomplexes containing *S. stercoralis* antigens.<sup>81</sup> Cardiac arrhythmias and arrest are exceedingly rare and have been attributed to direct myocardial damage caused by the migrating larvae<sup>82</sup> or to electrolyte imbalance precipitated by severe diarrhea.<sup>83</sup> The passage of larvae in semen and the presence of genital lesions<sup>84</sup> as well as multivisceral damage has also been attributed to strongyloidiasis.<sup>85</sup>

### Strongyloidiasis and Diseases of the Immune System

Since disseminated strongyloidiasis is a disease of the immunocompromised, persons with either inherited or

acquired immunodeficiencies would be expected to be particularly prone to this severe complication of infection.

### Acquired Immunodeficiency Syndrome

Traditionally, impaired immunity was thought to be one of the main factors regulating the development of *S. stercoralis* autoinfection. Therefore, frequent and severe infections with *S. stercoralis* were expected to emerge in patients with acquired immunodeficiency syndrome (AIDS). However, this has not happened, even in areas of the world where both *S. stercoralis* and AIDS are endemic, and in general, there does not appear to be a higher incidence of chronic strongyloidiasis with AIDS (see Chapter 133).<sup>86</sup> Even though sporadic cases of strongyloidiasis have been reported in patients with human immunodeficiency virus (HIV),<sup>87,88</sup> strongyloidiasis was removed from the list of AIDS-defining illnesses by the Centers for Disease Control and Prevention. However, some conditions that cosegregate with HIV infection are known to predispose to hyperinfection syndrome, including inanition and the use

**FIGURE 111-8** Left, fragment of larva (arrow) in the meninges of a man who died of disseminated strongyloidiasis. The egg in the inset was recovered from the cerebrospinal fluid when the patient was alive; this is a most unusual finding. Right, A larva detected during cytologic examination of a bronchoalveolar lavage specimen from the same patient.

of steroids.<sup>89</sup> In fact, the list of immunosuppressive diseases associated with hyperinfection are unified by the common denominator of corticosteroid therapy.<sup>89</sup> Nonetheless, *S. stercoralis* should be searched for and promptly treated in HIV-infected patients with a suggestive geographic history.

### HTLV-1 and Leukemia

Severe strongyloidiasis has often been reported to occur in some patients infected with both *S. stercoralis* and HTLV-1 (see Chapter 76).<sup>90</sup> An epidemiologic association between infection with HTLV-1 and strongyloidiasis was observed on the island of Okinawa<sup>91</sup> and in the West Indies.<sup>92,93</sup> It has been suggested that HTLV-1 infection may predispose to more severe strongyloidiasis and that infection with *S. stercoralis* may promote the progression of HTLV-1 infection to leukemia.<sup>37</sup> Several well-documented reports have shown that patients with HTLV-1 infection and no other known predisposition to precipitating factors have developed disseminated strongyloidiasis.<sup>94</sup> The nature of this association remains unexplained, but physicians should be aware of it, particularly when treating patients from areas of the world where there is an epidemiologic overlap between the two infections.

### Acquired Immunoglobulinopathies and Immunodeficiencies

No cases of disseminated strongyloidiasis have been reported in children with congenital immunodeficiencies. However, a few adults with acquired agammaglobulinopathy have been reported to have persistent extraintestinal *S. stercoralis* infection refractory to pharmacologic treatment. Although these individuals were producing large numbers of larvae in the stools and the sputum, they neither had symptoms that could be ascribed to strongyloidiasis nor developed the disseminated hyperinfection syndrome.<sup>35,95,96</sup>

## DIAGNOSIS

The diagnosis of strongyloidiasis is usually accomplished by detection of larvae in the stool. However, in a majority of uncomplicated cases of strongyloidiasis, the intestinal worm load is often very low and larval output is minimal.<sup>59,67</sup> Eosinophilia is usually the only indication of the presence of *S. stercoralis* infection but is mild (5% to 15%) and nonspecific (see Chapter 125).<sup>11,17,59,67,68</sup> In more than two thirds of cases, there are no more than 25 larvae per gram of stool.<sup>59,67</sup> Single examination of a stool sample has been shown to be negative in up to 70% of cases. Repeated examinations of stool specimens improve the chances of finding parasites; in some studies, diagnostic sensitivity increases to 50% with three stool examinations and can approach 100% if seven serial stool samples are examined.<sup>97</sup> Techniques utilized to discern larvae in stool samples include direct smear of feces in saline/Lugol's iodine stain, Baermann concentration, formalin-ethyl acetate concentration, Harada-Mori filter paper culture, and nutrient agar plate cultures.<sup>98–101</sup>

The examination of duodenal aspirate is reportedly very sensitive; this invasive method is recommended only in children when it is necessary to achieve a rapid demonstration of parasites.<sup>14,59</sup> Microscopic examination of a single specimen of

duodenal fluid is more sensitive than wet mount analysis of stool samples for the detection of larvae, identifying 76% of patients; the parasite was found exclusively in duodenal fluid (and not in feces) in 67% of patients.<sup>102</sup> The "string test," a gelatin capsule containing a string swallowed by the patient and retrieved after a few hours, enjoyed a brief period of popularity 2 decades ago but currently is used infrequently.<sup>103</sup> In some cases, histologic examination of duodenal or jejunal biopsy specimens may reveal *S. stercoralis* embedded in the mucosa.<sup>14</sup>

Detection of *S. stercoralis* larvae usually is easier in cases of hyperinfection because large numbers of worms are involved in disseminated infections.<sup>14,59,67</sup> The larvae can be identified in wet preparations of sputum, bronchoalveolar lavage fluid, bronchial washings and brushings, lung biopsies, and pleural fluid examined with either Gram's, Papanicolaou's, or acid-fast (Auramine O and Kinyoun) staining procedures.<sup>14,29,67</sup> Findings on chest films are usually variable; pulmonary infiltrates, when present, may be alveolar or interstitial, diffuse or focal, uni- or bilateral.<sup>104</sup> Lung consolidation, occasional cavitation, and even abscess formation have also been reported.<sup>56</sup> Varying chest x-ray pictures are explained by different types of bacterial superinfection, particularly gram-negative bacilli.<sup>56,104</sup>

A wide variety of immunodiagnostic assays have been tested over the last 2 decades with varying degrees of success. The long list includes skin testing with larval extracts, indirect immunofluorescence using fixed larvae, and radioallergosorbent testing for specific immunoglobulin E (IgE) and gelatin particle agglutination.<sup>14,59,67,68,105–108</sup> An enzyme-linked immunosorbent assay (ELISA) ("*Strongyloides* antibody") for detecting the serum IgG against a crude extract of the filariform larvae of *S. stercoralis* is also available at specialized centers.<sup>105,109,110</sup> The sensitivity and specificity of this ELISA can be improved if the sera samples are preincubated with *Onchocerca* antigens before testing.<sup>111</sup> The "*Strongyloides* antibody" test shows cross-reactivity with other helminths including filariae, *Ascaris lumbricoides*, and schistosomes, but for the general population in developed countries these are rarely in the differential diagnosis of symptomatic strongyloidiasis.<sup>14,59,67</sup> However, this does not hold true with respect to armed forces personnel, international travelers, immigrants, or residents of geohelminth endemic regions because they may have been exposed to "cross-reactive" antigens of other helminths in endemic areas. Furthermore, those helminths that contain "cross-reactive" antigens have the capability of long-term persistence within the host and the tendency to produce circulating antibodies that can be detected for many years after exposure. This test is unlikely to be available for wider use, because a constant supply of the *S. stercoralis* filariform larvae is needed to obtain the crude antigen preparation and because an abundant supply of *Onchocerca* antigens is required for presoaking of sera samples before an ELISA is performed. The major value of serology is the provision of a screening test that, if positive, can stimulate further searches for the parasite.<sup>14,67</sup> Positive ELISA serology does not distinguish prior from current infection.

In summary, stool examinations are currently the primary technique for detection of *S. stercoralis*. If special techniques are not available, several specimens collected on different days should be examined when the diagnosis is strongly suspected.

## TREATMENT

Nematodes do not replicate within their definitive hosts (with the very limited exceptions of *S. stercoralis* and *Capillaria philippinensis* [see Chapter 106]). Therefore, anthelmintic treatment that reduces the worm burden for most nematodes below the level at which clinical disease can develop usually is sufficient.<sup>14,59,68</sup> However, in *S. stercoralis* infection, only the complete eradication of parthenogenetic adult females and autoinfective larvae removes the danger of potentially life-threatening hyperinfection.<sup>14,59</sup> Thus, all patients with strongyloidiasis (even asymptomatic patients) require treatment.<sup>86</sup> The poor sensitivity of diagnostic stool examination makes it even more difficult to determine the effectiveness of the treatment, because a true cure cannot be pronounced based on a negative follow-up stool examination.<sup>59,67</sup> In some instances, serologic tests and changes in eosinophil counts may serve as useful markers of treatment success.<sup>59,67</sup> Generally, three anthelmintics have been used to treat strongyloidiasis with varying degrees of efficacy.<sup>86</sup>

### Ivermectin

Ivermectin is derived from  $\beta$ -avermectins (monocyclic lactones) that are produced by *Streptomyces avermitilis*. The mode of action of this orally administered broad-spectrum anthelmintic is through selective binding with glutamate-gated chloride ion channels in nerve and muscle cells that causes hyperpolarization of the nerve and muscle cell membranes, resulting in paralysis and death of the worm.<sup>86</sup> The plasma half-life of this drug is 16 hours, and it is metabolized in the liver.<sup>86</sup> A consensus is developing about ivermectin being the ideal drug for the treatment of intestinal and disseminated strongyloidiasis.<sup>112–117</sup> Ivermectin has a cure rate of 64% to 100% after a single dose.<sup>118</sup> Ivermectin has been registered recently as the drug of choice in the World Health Organization's Essential Drug List for the treatment of *S. stercoralis*. The standard dosage is 200  $\mu$ g/kg per day, given orally (1 to 2 days), for intestinal infections.<sup>117</sup> The same regimen is recommended for adults and children (>15 kg). Adequate and well-controlled clinical studies have not been conducted to determine the optimal dosing regimen in immunocompromised patients or patients with the disseminated disease; it may be necessary to prolong (e.g., 7 to 10 days) or repeat the therapy.<sup>117</sup> Ivermectin administered as an enema may be of some benefit in patients with severe strongyloidiasis who are unable to absorb or tolerate oral therapy.<sup>119</sup>

### Thiabendazole

Historically, thiabendazole has been the drug of choice for the treatment of strongyloidiasis, despite frequent gastrointestinal and neuropsychologic side effects and a high relapse rate. Thiabendazole has a cure rate of 50% to 94% and may not be effective in disease that is disseminated beyond the gastrointestinal tract.<sup>19,117,118</sup> Thiabendazole is a broad-spectrum drug for intestinal nematodes and acts by inhibiting helminth-specific mitochondrial fumarate reductase. Thiabendazole is absorbed rapidly, and peak plasma concentration is reached within 1 to 2 hours after the oral

administration of a suspension.<sup>86</sup> The standard dosage is 50 mg/kg per day orally in two doses (maximum 3 g/day every 2 days; this dosage is likely to be toxic and may have to be decreased).<sup>117</sup> Pediatric dosages are same as adult dosages.<sup>117</sup>

### Albendazole

Albendazole is an orally administered broad-spectrum anthelmintic with variable therapeutic efficacy. It is poorly absorbed from the gastrointestinal tract because of its low aqueous solubility, and it has a cure rate of 36% to 75%.<sup>118,120</sup> Maximal plasma concentrations of albendazole sulfoxide are achieved typically 2 to 5 hours after dosing.<sup>86</sup> The principal mode of action for albendazole is its inhibitory effect on tubulin polymerization, which results in the loss of cytoplasmic microtubules.<sup>86</sup> The standard dosage for adults (>60 kg) is 400 mg orally after meals twice a day for 3 days, 7 to 10 days for hyperinfection; for children (<60 kg), 15 mg/kg per day orally after meals in two doses for 3 days, 7 to 10 days for hyperinfection (maximum total daily dose 800 mg).<sup>117</sup>

For hyperinfection strongyloidiasis, the concurrent discontinuation or tapering of corticosteroids is necessary, as is appropriate antibiotic/antifungal treatment of the infections that usually accompany extraintestinal strongyloidiasis. Even with this regimen, more than two thirds of the patients with dissemination succumb to the disease.

## PREVENTION AND CONTROL

Strategies for the control of strongyloidiasis in endemic areas are similar to those developed for the control of other geohelminthiasis. Appropriate methods of human fecal sanitation and sewage disposal and the use of shoes are of paramount importance. For at-risk individuals, virtually all cases of fatal hyperinfection and dissemination could be prevented by suspecting, detecting, and treating chronic, well-regulated infections in patients who are candidates for immunosuppression, particularly from any form of corticosteroid therapy. Unexplained eosinophilia (see Chapter 125), prior—even remote—histories of potential exposures to contaminated soil in *Strongyloides* endemic regions, or compatible cutaneous or gastrointestinal symptoms, albeit often nonspecific, of chronic strongyloidiasis should prompt consideration of underlying strongyloidiasis prior to corticosteroid treatment.

The principal transmission mode of *S. stercoralis* is that of a geohelminthiasis, through the contamination of soil with infected feces. In ordinary hygienic conditions, human-to-human transmission does not appear to occur. Thus, the infection can be prevented by implementing public health measures aimed at ensuring proper disposal and treatment of excrement and by avoiding skin contact with contaminated soil. In institutional facilities caring for those with fecal incontinence or contamination (e.g., the mentally retarded), filariform *Strongyloides* larvae in feces can cause nosocomial or intrainstitutional spread of infection. The authors also recommend that strongyloidiasis be a reportable disease in areas of Europe and North America where autochthonous infections have been reported to ensure adequate treatment of infected patients and to maintain surveillance of the number of cases.

## 112

# Introduction to Tapeworm Infections

MURRAY WITTNER  
CLINTON WHITE  
HERBERT B. TANOWITZ

Tapeworm infections are among the oldest recognized afflictions of humanity.<sup>1,2</sup> For example, recent phylogenetic studies<sup>2</sup> suggest that the ancestors of modern humans may have acquired taeniid tapeworm infections about 2 million years ago, from the animals they consumed, and eventually passed the infection on to bovine and porcine hosts about 10,000 years ago.

The Cestoda, or tapeworms, are a class in the phylum Platyhelminthes (flatworms) and except for the ciliated embryo of the order Pseudophyllidea are exclusively parasitic for their entire life.<sup>3</sup> In the adult stage, they live exclusively in the alimentary canal, including occasionally the bile ducts, gallbladder, and pancreatic duct. They infect members of all vertebrate classes although members of the subclass Cestodaria and several neotenic species attain adulthood in invertebrates (oligochaetes). However, cestode larvae often infect both vertebrates and invertebrates.

With few exceptions, the characteristic feature of adult tapeworms is their elongated (i.e., tapelike) dorsoventrally flattened structure. Their outer covering, or tegument, allows the passage of both nutritive and waste material. The absorptive surface of the tegument is amplified by the formation of many cytoplasmic extensions similar to microvilli of enterocytes. Numerous studies have shown that tapeworms actively take up and utilize carbohydrates from the intestinal lumen as their major, if not sole, energy source, with the production largely of lactate, propionate, and succinate as end products. There is active uptake of  $\alpha$ ,DL amino acids across the tegumental membrane.<sup>4</sup> Diffusion appears to play a minor role.

Of the various orders of cestodes, there are two that include important parasites of humans and domestic and marine mammals. Their adult stage resides in the lumen of the small intestine and the larval stage in various tissues of the intermediate host. The order Pseudophyllidea is characterized by the presence of a scolex, or attachment organ, containing two sucking grooves. Examples of this group are members of the genus *Diphyllobothrium* and include *D. latum* (the broad or

fish tapeworm), *D. pacificum*, and worms that infect humans only at the larval stage such as *Spirometra* (i.e., sparganosis). The order Cyclophyllidea, to which all other tapeworms that parasitize humans belong, is characterized by a scolex that possesses four suckers. This group includes those belonging to the genus *Taenia*, examples of which are the beef and pork tapeworms, *Hymenolepis*, *Bertiella*, *Dipylidium*, *Mesocestoides*, *Raillietina*, *Inermicapsifer*, and *Echinococcus*.

The life cycles of the Pseudophyllidea involve a minimum of three hosts. Those of the Cyclophyllidea generally require two, although in some species the definitive host can also serve as the intermediate host. Medically important tapeworms range in size from the minute dog tapeworm, *Echinococcus granulosus*, which generally consists of a scolex and three or four segments, to *Taenia saginata*, reported to reach 25 to 30 meters in length.

Adult tapeworms typically possess an anterior scolex or head that may be modified or adorned with structures or organelles that serve as organs for attachment to the small intestinal mucosa. In the Pseudophyllidea, the structures that function for attachment are termed bothria, which are two shallow sucking grooves whose gripping power is feeble.<sup>5</sup> Some species of Cyclophyllidea, in addition to having four sucking disks or acetabula, possess hooklets that encircle the top of the scolex or are mounted on a protrusion known as the rostellum (Fig. 112-1). In some species, such as *Hymenolepis*, the rostellum is protrusible. The distal portion of the scolex, termed the "neck," is an area of intense metabolic activity, which in most groups of tapeworms is the zone from which new segments or proglottids proliferate and form a chain of proglottids or strobila. Clinically, the scolex is highly significant since therapy is aimed at its destruction or elimination, inasmuch as failure to do so will result in regrowth of the entire tapeworm. Usually the most proximal proglottids are immature. They contain only the earliest rudiments of the organs that are present in the mature proglottids. Those further distal become mature proglottids and contain one set, and in some species two complete sets, of male and female sex organs, that is, they are hermaphroditic. The distal most segments are filled with eggs and are termed "gravid proglottids," which in cyclophyllidean cestodes the sex organs have atrophied, leaving the segment occupied largely by a uterus filled with eggs.<sup>6</sup>

Except for the coracidium, the tapeworm egg is the only stage that interacts with the external environment. For diagnostic purposes, eggs are characteristic. In members of the genus *Diphyllobothrium*, eggs are discharged through a muscular uterine pore and, therefore, they are regularly found in the feces. However, in many cyclophyllidean species, the gravid proglottids split and the eggs are released through rents in the proglottids. The eggs of other tapeworms, such as *Hymenolepis nana* and *H. diminuta* are found in the stool after disintegration of the gravid prognostics, whereas those of the beef tapeworm, *Taenia saginata*, are often not found in the stool because they are passed out within intact segments. In fact, a "Scotch tape" preparation, similar to that used for

**FIGURE 112-1** *Taenia solium* scolex. RH, rostellum; SU, sucking disks, or acetabula; VP, young proglottids.

the diagnosis of pinworm infection, is often more reliable in finding *T. saginata* eggs. Eggs of the diphyllbothriid tapeworms are operculate, resembling that of many trematodes, and hatch in water to release a free-swimming larva, the coracidium. Cyclophyllidean tapeworm eggs all contain a fully developed hexacanth (six-hooked) embryo, the onchosphere. The embryonic envelope that surrounds this onchosphere comprises what is generally referred to as the egg shell, and its morphology is often diagnostic of the species. With the single exception of *Hymenolepis nana*, tapeworms that infect man require one or more intermediate hosts to complete their life histories. The life cycle of diphyllbothriid cestodes involves two or more intermediate hosts. The first stage larva or coracidium are ingested by water fleas or copepods, and develop into proceroid larvae in the body cavity of these hosts which, while retaining their embryonic six hooklets, show evidence of developing bothria. When infected copepods are ingested by appropriate piscine hosts, the proceroid enters the musculature of the fish, where it becomes a plerocercoid or sparganum larva. Interestingly, the latter may have a number of transfer or paratenic hosts. Thus, a plerocercoid that has developed in a minnow may next parasitize a somewhat larger fish, and may even pass through a series of such transitory domiciliary relationships until its final piscine host is ingested by a suitable mammal, in which it will become an adult.

Some cestodes only infect humans in the larval stage.<sup>7</sup> These larval stage infections are primarily zoonoses for which humans are incidental or dead-end hosts. For example,

sparganosis is caused by infection with the the plerocercoid (sparganum) of *Spirometra mansonoides*, which migrates through various tissues. Other tapeworms can infect humans in both the adult and larval stages. For example, *Taenia solium* is the definitive host for the adult tapeworm but ingestion of ova may result in cysticercosis, a larval form. In the genera *Multiceps* (= *Taenia*) and *Echinococcus*, larval development results in considerable multiplication. Therefore, when ingested by a suitable definitive host, there may be large numbers of adult worms produced.

Adult tapeworm infections may persist for many years or even for the life of the host. During this period, it may be relatively asymptomatic or cause persistent symptoms and deprive the host of important and/or essential nutriment. However, these infections are usually well tolerated. Infections with larval stage parasites often cause serious or fatal disease and can be of great economic consequences. Until recently, these serious larval infections have gone undiagnosed. The introduction of computed tomography (CT) scanning has resulted in a fourfold increase in the diagnosis of neurocysticercosis in Los Angeles. Similarly, the introduction of imaging techniques have led to an increased recognition of neurocysticercosis and hydatid disease throughout Asia, Africa, and Latin America.

The diagnosis and management of tapeworm infections is constantly improving. While the routine examination of stools for parasite life stages is most important, the detection of parasites by immunodiagnostic and molecular approaches have improved the diagnosis of both adult and larval infections.<sup>8</sup> These tests have included the detection of coproantigens to adult stage taeniasis and has had limited availability although it is highly specific and sensitive. The diagnosis of larval tapeworm infections has been markedly enhanced by the use of imaging techniques including magnetic resonance imaging (MRI) and CT of the brain for neurocysticercosis.<sup>9</sup> Similarly, image analysis of hydatid disease of the liver and lung by CT, MRI, and ultrasonography has become routine diagnostic procedures.

The management of tapeworm infections is constantly undergoing change. The medical treatment of both adult tapeworm and larval with benzimidazole compounds and praziquantel<sup>10</sup> has become an important adjunct to surgery and in some instances has supplanted invasive procedures. Cystic hydatid disease is often managed by a combination of percutaneous aspiration and/or surgery and drug therapy. Alveolar hydatid is most often managed by surgery and drug therapy. The role of drug therapy in the treatment of neurocysticercosis continues to be examined, as are the roles of surgery, including endoscopic surgery and the placement of ventricular shunts.

The development of safe, effective, and inexpensive vaccines to protect against several of the economically important tapeworm infections has been an important area of investigation.<sup>11</sup> Recombinant onchosphere-subunit peptide vaccine candidates have been produced or identified for use against several important taeniid cestodes, including *T. saginata*, *T. solium*, and *E. granulosus*. Several of these vaccines are undergoing clinical trials. Major strides have been made in the molecular and immunodiagnosis of important human and animal tapeworm infections.

## ■ Neurocysticercosis

### INTRODUCTION

Neurocysticercosis is a neurologic infection caused by the larval stage of the tapeworm *Taenia solium*. The cysticercus is the larval form of the parasite. The ancient Greeks originally identified these forms in meat, which they termed *cysticerri* (meaning “cyst-tail”).<sup>1</sup> Paranolus first identified human neurocysticercosis in 1550. However, 19th-century European investigators defined the relationship between the larval cysticercus form and the adult tapeworms. Küchenmeister demonstrated that prisoners fed cysts from infected pork developed tapeworms. Van Beneden demonstrated that pigs developed cysticerri when fed on *Taenia* eggs obtained from gravid proglottids. By the early 20th century, large case series had been published that described infection in hundreds of patients, identifying nearly all of the major clinical manifestations of disease.

Nevertheless, it was only in the 1980s with the availability of noninvasive neuroimaging scans that neurocysticercosis began to be recognized as a major cause of neurologic disease. When computed tomography (CT) scans were used, many patients with seizure disorders or hydrocephalus, which would otherwise have been thought to be idiopathic, were recognized as having neurocysticercosis. These findings led to the current recognition that neurocysticercosis is a major cause of neurologic disease worldwide.

### AGENT

*Taenia solium*, the cause of human cysticercosis, is typical of cestode parasites; there are separate adult (the intestinal tapeworm) and larval (metacestode or cysticercus) forms. Humans can host both forms of the parasite in contrast to most other cestodes. The *T. solium* life cycle includes two obligate hosts, each with a different form of the parasite. In the normal life cycle, the larval form (or cysticercus) is found primarily in muscle of the pig, the intermediate host. In the 19th century, the cysticercus form was given a separate taxonomic name, *Cysticercus cellulosae*. The latter term reflected an incomplete understanding of the biology of the parasite and should no longer be used. Humans are the obligate definitive host for

the adult, tapeworm form. Humans become infected with the tapeworm (taeniasis) by ingesting undercooked pork infested with *T. solium* cysticerri. After ingestion, the scolex evaginates. The scolex is about 1 mm in diameter and contains four suckers and two rows of hooklets, which facilitate attachment to the small intestines. New proglottids arise at the base of the scolex, and the older proglottids form a chain that can reach a length of up to 30 feet, usually 6 to 12 feet. The larger, more-mature proglottids are found at the distal end. The mature proglottids have an off-white color. They are approximately 1 cm wide, 1 cm long, and 1 mm thick. The proglottids are hermaphroditic with testes and ovaries producing fertilized ova. Intact proglottids and/or ova are shed in the stool. Tapeworm carriers note few symptoms other than possibly noting proglottids in the stool, which may be confused with noodles. Excretion is intermittent, such that stool examinations for ova or parasites are usually negative.

Porcine cysticercosis is endemic in regions where pigs have access to human fecal material. The pigs ingest the ova or proglottids from the tapeworm carrier. The eggs hatch in the upper intestines, releasing the oncospheres (invasive larvae). The oncospheres penetrate the intestinal mucosa using their hooklets and excretory proteases, enter the bloodstream, and migrate to the tissues, where they mature into cysticerri. In muscle, the cysticerri appear as translucent, oval cysts, approximately 1 cm in diameter. The scolex is invaginated and appears as a 1 to 2 mm white nodule along one side of the cyst wall.

Human cysticercosis follows ingestion of ova from a tapeworm carrier. Close personal contact with, or perhaps food preparation by, a tapeworm carrier is noted in most cases. Following ingestion, the oncospheres penetrate the mucosa and are carried to a number of organs. For example, cysticerri have been identified in skeletal and cardiac muscle, subcutaneous tissue, and even lung tissue. However, in most of these locations, they cause few symptoms and spontaneously degenerate, which may lead to formation of calcified granulomas. Most disease results from the minority of parasites that invade the central nervous system, including the brain, cerebral ventricles, or eye. Cysticercosis involving the nervous system is termed *neurocysticercosis* (NCC). While cysticercosis is not acquired directly from eating pork, tapeworm carriers can infect themselves, probably by the fecal-oral route. The fact that pork ingestion is not the direct cause of human cysticercosis is illustrated by cases of cysticercosis that have occurred among an Orthodox Jewish community in New York City and vegetarians in India.<sup>2-4</sup>

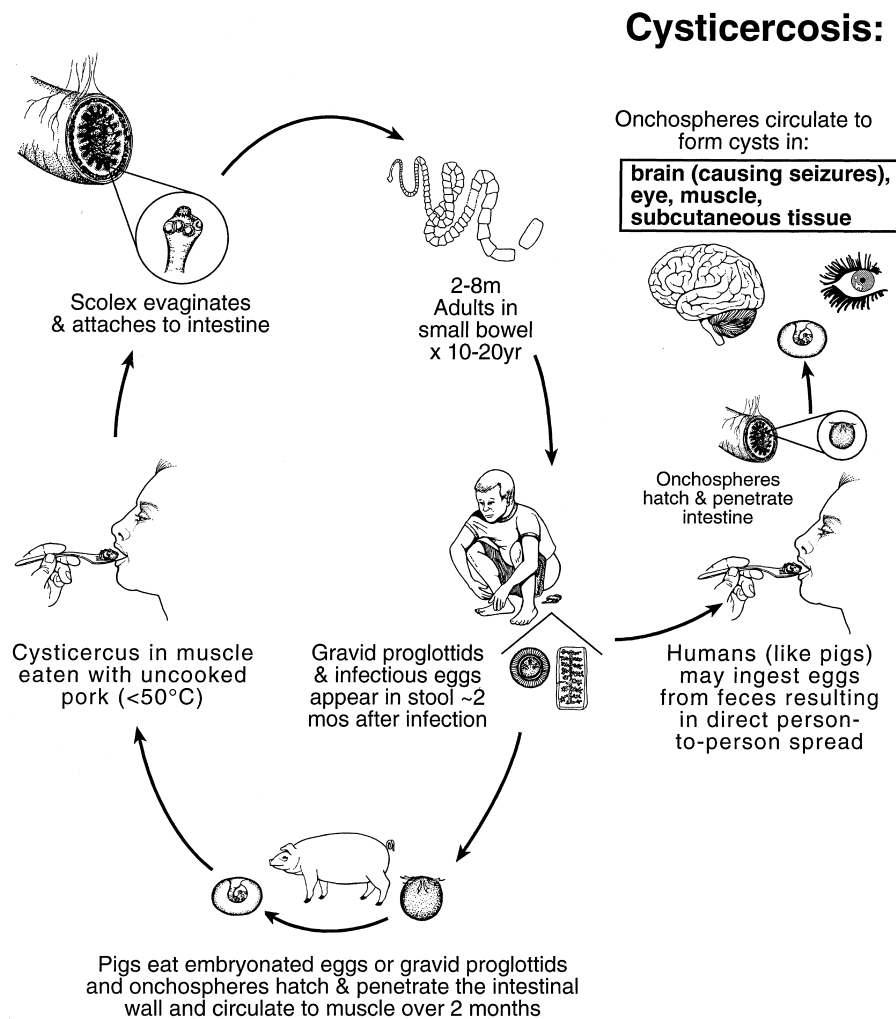

### EPIDEMIOLOGY

The epidemiology of human cysticercosis and tapeworm infections has been elusive. For neurocysticercosis, the clinical presentation overlaps with a number of other common diseases (e.g., idiopathic epilepsy, tumors). The parasites are not easy to identify since they are not present in blood or stool. Definitive diagnosis requires expensive neuroimaging studies, which are not widely available to populations at highest risk, and serodiagnostic techniques have been plagued in the past by poor sensitivity and problems with specificity. Moreover, poor understanding of the meaning of antibody reactions and inaccurate comparisons (e.g., comparing seroprevalence in general populations to epileptic patients) have further confused

# Pork Tapeworm

## *Taenia solium*

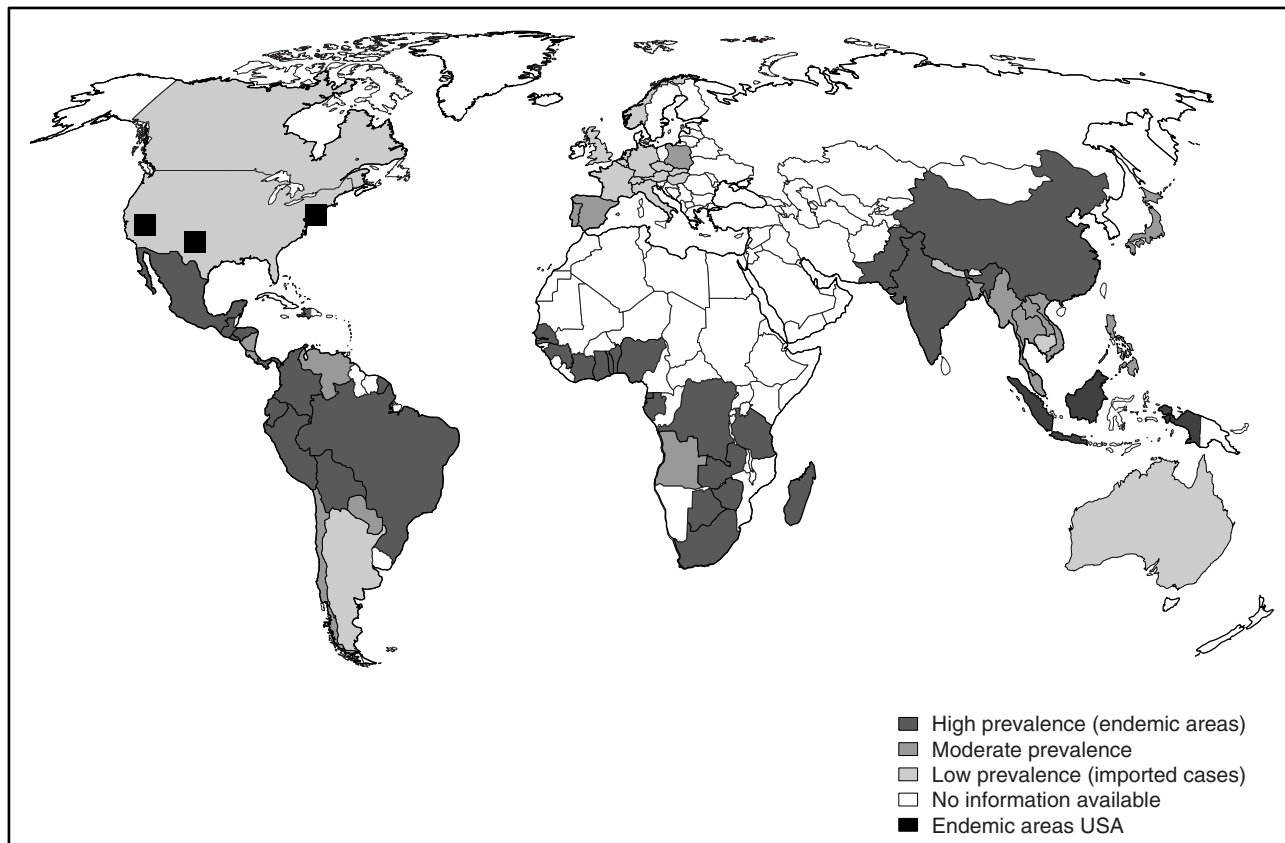

the interpretation of serologic data. Thus, the importance of this infection has generally been significantly underestimated.

*T. solium* is endemic in all areas of the world where pigs are raised under conditions in which they have access to human fecal material. Studies have documented significant endemicity in Latin America, Eastern Europe, sub-Saharan Africa, India, and elsewhere in Asia.<sup>5,6</sup> Infection was highly endemic throughout Europe during the 19th century. Occasional cases are still acquired in eastern and southern Europe. The heavy burden of disease was appreciated after the introduction of computerized imaging studies. This was noted among Latin American immigrants to the southwestern United States, where the introduction of CT scanning was followed by a fourfold increase in the number of cases of NCC.<sup>7</sup> Subsequent studies from Mexico, Peru, and Ecuador documented that up to half of patients with adult-onset seizures had evidence of NCC by neuroimaging studies.<sup>8-10</sup> Population-based surveys in rural villages have documented a high prevalence of infection throughout Latin America, with rates of seizure disorders ranging from 11 to

30 per 1000 and CT abnormalities consistent with NCC noted in up to 70% of those with seizures.<sup>11-15</sup> Similar studies have also demonstrated NCC in a high proportion of African patients with seizures, with the disease prevalent throughout sub-Saharan Africa.<sup>16-19</sup>

Neurocysticercosis was identified in a significant number of British soldiers stationed in India in the early 20th century,<sup>20</sup> but it was infrequently diagnosed in the native population of India prior to the 1990s. When neuroimaging studies were performed on patients in India with seizures, most patients were noted to have focal abnormalities. For example, among 991 patients with focal seizures in southern India, CT scans demonstrated abnormalities consistent with NCC in 40%, including lesions diagnosed as active cysticercosis, typical calcifications, or single-enhancing CT lesions (consistent with cysticercal granulomas).<sup>21</sup> Similar data were noted for children with seizures and in patients from northern India.<sup>22,23</sup> The single-enhancing CT lesions were frequently attributed to tuberculosis or to the effects of seizures. However, excisional

biopsies demonstrated that nearly all showed histopathologic evidence of cysticercosis.<sup>24</sup> For example, over half of 401 patients presenting with a single-enhancing lesion were diagnosed with NCC.<sup>25</sup> Neurocysticercosis is increasingly recognized in other parts of Asia including Indonesia, Southeast Asia, China, and Korea.<sup>26</sup>

## DISEASES

The clinical presentation, pathogenesis, management, and prognosis of *T. solium* infections vary markedly depending on the location and number of cysticerci and the associated host response. Thus, neurocysticercosis should be regarded as a spectrum of illnesses rather than a single disease entity. NCC is typically separated into parenchymal and extraparenchymal disease based on whether or not there is involvement outside of the brain tissues. Extraparenchymal cases primarily include involvement of the subarachnoid space and ventricles. Pathologic studies show that many of the cysticerci found over the brain convexity are actually located in gyri, but clinically and radiologically the manifestations are indistinguishable from parenchymal cases. Extraparenchymal cases may also involve the spinal subarachnoid space, the spinal cord, or the eye. Many patients, particularly those with large numbers of parasites, will present with mixed forms. For example, most patients with subarachnoid NCC also have one or more parenchymal cysticerci.

Clinically, parenchymal neurocysticercosis usually presents with seizures and carries a favorable prognosis. Headache can also be a prominent feature. Most severe or fatal cases of NCC are due to extraparenchymal disease.<sup>27,28</sup> Subarachnoid and ventricular disease are often complicated by increased intracranial pressure and hydrocephalus. Thus, patients may present with symptoms of increased intracranial pressure (e.g., headache, dizziness, altered mental status, and visual changes due to papilledema). Extraparenchymal disease often requires surgical therapy and can be fatal if not managed properly. Most schemes also separate neurocysticercosis into inactive and active infection. Inactive disease does not have evidence of viable infection; disease is thought to result from the residua of prior infection. Active infection includes cases with both viable cysticerci and those with degenerating parasites. Some authors, however, propose separating degenerating (transitional) forms from viable cysticerci and using the term *active* for the latter.<sup>29</sup> Clinical cases are usually classified by neuroimaging studies.<sup>29–31</sup>

## Parenchymal Neurocysticercosis

### Inactive (Parenchymal Calcifications)

The characteristic of inactive neurocysticercosis on neuroimaging studies is parenchymal calcifications. The calcifications are typically 2 to 10 mm in diameter, well defined, and solid (Fig. 113-1). The calcified lesions are thought to represent

**FIGURE 113-1** Calcified cysticercal lesion with surrounding edema revealed by CT scan (arrow).

fibrotic reactions to prior active infection that have calcified (calcific stage). Patients frequently present with seizures.<sup>32</sup> Few will have focal abnormalities on electroencephalogram (EEG) studies.<sup>33,34</sup> In hospital settings, patients with residual calcifications are more likely to have recurrence of seizures if antiepileptic drugs are withdrawn.<sup>35,36</sup> They usually should be treated with antiepileptic therapy indefinitely. Recent magnetic resonance imaging (MRI) studies have documented that some patients with NCC and seizures have calcified lesions with associated enhancement and edema.<sup>37–40</sup> There is no evidence that these lesions are associated with viable parasites. Instead, the enhancement may result from breakdown of the calcified granulomas with antigen release resulting in restimulation of host inflammation.<sup>38</sup>

### Active

Active parenchymal infection is the most common form of NCC in nearly all case series. The vast majority of patients with symptomatic parenchymal NCC and seizures have neuroradiologic evidence of parasite degeneration and/or host inflammation such as edema or contrast enhancement (Fig. 113-2).<sup>41,42</sup> Symptoms are thought to result from the host inflammatory response, which will eventually subside. By contrast, noninflamed cysts cause few symptoms, even when they are numerous.<sup>43</sup> Thus, symptomatic infection likely occurs when one or more cysticerci can no longer control the host inflammatory and immune responses.

Seizures are the main clinical manifestation of parenchymal infection.<sup>44,45</sup> The seizures are often generalized or focal with secondary generalization, but may also be focal.<sup>33,44–46</sup> EEG studies for patients with active disease may reveal focal abnormalities, particularly in those with single

**FIGURE 113-2** Parenchymal cysticercus revealed as a ring enhancing lesion (arrow).

inflamed cysticerci.<sup>33,34</sup> Seizures associated with active parenchymal cysts are likely caused by active parenchymal inflammation. Seizures can usually be controlled during treatment with antiepileptic drugs and often resolve after normalization of imaging studies as the inflammation subsides.<sup>45,46</sup> Relapse is, however, frequent.

Some patients present with large numbers of inflamed cysticerci, with diffuse cerebral edema, raised intracranial pressure, seizures, and altered mental status. This is termed *cysticercal encephalitis*.<sup>47,48</sup> This form is more common in children than adults and more common in women than men. Treatment is mainly directed at controlling the cerebral edema.

## Extraparenchymal Neurocysticercosis

### Ventricular NCC

In recent series, 10% to 20% of patients with NCC had cysticerci in the ventricles.<sup>31,42</sup> These cysticerci can obstruct cerebrospinal fluid (CSF) flow causing hydrocephalus. The cysticerci are found in any of the ventricles. Older series noted most of the ventricular cysticerci in the 4th ventricle, but this may have reflected more severe disease when the cysticerci are in that location. In most cases, the cysticerci cause symptoms while still viable.<sup>49</sup> Since viable cysticerci have thin walls with cyst fluid isodense with CSF, they may be difficult to detect. CT scanning usually only shows evidence of obstructive hydrocephalus or distortion of the shapes of the involved ventricle. Intraventricular cysticerci are frequently visible on MRI (Fig. 113-3).<sup>50,51</sup> However, the findings are subtle and can be missed by inexperienced observers. These patients may also have parenchymal cysticerci.

Patients with ventricular neurocysticercosis present with symptoms or signs of raised intracranial pressure. Symptoms may include nausea or vomiting, altered mental status, visual

**FIGURE 113-3** Two cysticerci in the lateral ventricle revealed by MRI.

changes, or dizziness. The onset varies and can be abrupt (due to acute obstruction), intermittent, or gradual. Cysticerci may form a ball valve in the foramina that may come and go with position changes. Cysticerci in the 4th ventricle have been associated with acute obstructive hydrocephalus that can lead to drop attacks.

#### Active Subarachnoid NCC

When patients have cysticerci in the gyri of the cerebral convexities, the radiological appearance, clinical presentation, and pathogenesis overlap with active parenchymal NCC. However, the cysts may be slightly larger and resolution is less frequent after antiparasitic chemotherapy.

Cysticerci in the fissures (especially the Sylvian fissure) can enlarge to several centimeters in diameter, termed *giant cysticerci*.<sup>52</sup> Isolated cysticerci in the fissures carry a similar prognosis to parenchymal cysts with symptoms resulting from parenchymal inflammation. In some cases, however, the cysts may enlarge causing mass effects such as midline shift. Frequently, giant cysticerci are accompanied by cysticerci in the parenchyma or basilar cisterns. The giant cysticerci are readily visualized by CT or MRI, but the accompanying basilar cysticerci may not be seen as easily. Cysticercosis of the basilar cisterns carries a grave prognosis. Numerous cysticerci may fill the basilar cisterns (Fig. 113-4). Patients with numerous cysticerci in the basilar cisterns can present with communicating hydrocephalus due to CSF outflow obstruction or arachnoiditis. Basilar arachnoiditis appears on imaging studies as focal or diffuse meningeal enhancement or vasculitis and can be complicated by strokes due to vasculitis.<sup>53,54</sup>

#### Inactive Extraparenchymal Neurocysticercosis

Inactive infection may also present with hydrocephalus in patients with prior arachnoiditis or granular ependymitis. The resulting obstruction of CSF flow (e.g., aqueductal stenosis) or CSF outflow obstruction can cause symptoms of hydrocephalus.

#### Spinal NCC

Only about 1% of patients with NCC have recognized spinal involvement.<sup>31,42</sup> Most cases of spinal NCC result from cysticerci in the subarachnoid space.<sup>27</sup> Initially, spinal subarachnoid cysticerci are free-floating, and they may move between levels. When the cysticerci degenerate, they eventually become fixed at one level. The accompanying inflammation may cause mass effect with obstruction of flow on myelogram. The clinical manifestations include radicular paresthesias or pain, which may progress to myelopathy with bowel or bladder incontinence and paraparesis. Cysticerci are rarely intramedullary, with cord compression from mass effect or accompanying inflammations.

#### Other Forms of Cysticercosis

Cysticercosis can involve the orbit and/or eye. The most common presentation is ptosis related to involvement of the extra-ocular muscles.<sup>55,56</sup> Ocular involvement is usually subretinal, but can be intravitreal or subconjunctival (Fig. 113-5).<sup>56-59</sup> Patients may present with altered vision. Subconjunctival cysts may spontaneously extrude. Intra-ocular disease usually requires surgical removal.

Cysticerci may involve the muscles. Only rarely do they cause more than minor symptoms. Soft tissue calcifications are frequently found in all forms of cysticercosis. Cysticerci can involve the subcutaneous tissues, where they present as a palpable, painless, and mobile cystic lesions that can be confused with sebaceous cysts. As the cysticerci degenerate, the lesions may become firm nodules or later resolve. Subcutaneous disease

**FIGURE 113-4** Cysticerci in the subarachnoid space of the basilar cisterns revealed by MRI.

**FIGURE 113-5** A, Subretinal cysticercosis at the macular area with overlying retinal edema. B, Cysticercosis of the eye. (A, Courtesy of Robert Ritch, MD, New York Eye and Ear Infirmary, New York, NY. From Teekhasaene C, Ritch R, Kanchanaranya C: Ocular parasitic infection in Thailand. *Rev Infect Dis* 8:350–356, 1986.)

is rarely noted in the Western Hemisphere, but is commonly noted in Asia.

### Mixed Forms

Clinical cases, especially those involving large numbers of cysticerci, often include more than one of the preceding forms. The pathogenesis and presentation may reflect each location. For example, patients who present with seizures will usually have parenchymal cysticerci. However, some also have cysticerci in the basilar cisterns that can progress to hydrocephalus later if not properly managed.

### Other Syndromes

Headaches are common among patients with NCC and may be seen with parenchymal, ventricular, or cisternal NCC. Headaches may be hemicranial or bilateral.<sup>60,61</sup> The headaches can be confused with uncomplicated migraines or tension headaches. The pathogenesis is also variable. In some cases, headache is the initial symptoms of raised intracranial pressure. The association of parenchymal NCC with migraine-like headaches suggests vascular involvement.<sup>60</sup>

Neurocognitive defects have been described with cysticercosis.<sup>62</sup> Infected children are thought to suffer from learning disabilities.<sup>63</sup> There also appears to be an association of cysticercosis with depression and occasionally psychotic episodes.<sup>64</sup> By contrast, acute alterations of mental status usually reflect ongoing seizures or hydrocephalus. In our experience, altered mental status that does not resolve after a reasonable postictal period usually results from hydrocephalus.

## PATHOGENESIS AND IMMUNITY

Cysticerci reach their final size within a few weeks of invasion into the central nervous system (CNS). However, there is a period of several years between infection and onset of symptoms.<sup>20,65</sup> In autopsy studies of individuals who died of other causes, cysticerci, when present, have an appearance similar to

the viable cysticerci from pigs.<sup>66</sup> By contrast, cysticerci from patients who died with seizures demonstrate a prominent inflammatory infiltrate. The parasites elaborate a number of molecules that modulate or suppress the host inflammatory and immune response.<sup>67</sup> For example, parasite excretory proteases cleave CD4 from the surface of host lymphocytes, degrading immunoglobulin and cytokines such as interleukin (IL)-2.<sup>68</sup> Parasites also produce prostaglandins that modulate the host response.<sup>69</sup> Parasite secretory protease inhibitors block complement activation and decrease cytokine production and leukocyte chemotaxis.<sup>70–72</sup>

By contrast, an animal model has demonstrated that the seizures are induced by the host granulomatous response rather than the parasite per se.<sup>73</sup> Clinical studies suggest that after months to years, the cysticerci lose their ability to control the host response and are attacked by host inflammatory cells composed of mononuclear cells, with variable numbers of eosinophils and neutrophils.<sup>74,75</sup> The tissues pass through a series of stages of inflammation.<sup>76,77</sup> These cells elaborate type 1 cytokines such as IL-12, interferon gamma, and IL-2 as well as variable amounts of type 2 cytokines (e.g., IL-4 and IL-5).<sup>74,75,78</sup> Proinflammatory cytokines such as IL-1, tumour necrosis factor (TNF)- $\alpha$ , and IL-6 are also found in the spinal fluid from active cases.<sup>79,80</sup> The wall gradually degenerates, the cyst fluid increases in density and agglutinates, and the cyst cavity is invaded by inflammatory cells (colloid stage). The cysticercus subsequently is encased by fibrosis with collapse of the cyst cavity (granular-nodular stage). The fibrotic granuloma may calcify (calcified stage). Even the calcified lesions can be associated with inflammation. Interestingly, parts of the degenerating cysticercus (e.g., hooklets) may still be identified in the calcified lesion.

### Imaging Findings

Similar steps in progression have been noted on neuroimaging studies.<sup>81,82</sup> Invasion of the central nervous system and early cysticercal development may cause focal edema or enhancement. Viable cysticerci reveal the cyst cavity as an

area of decreased density, isodense with cerebrospinal fluid. The scolex may be seen as a mural nodule. The cyst wall is thin and isodense with brain parenchyma, lacks surrounding edema or contrast enhancement, and is usually not identifiable. When the cysticercus becomes inflamed, the cyst wall density increases. The cyst wall may enhance with contrast and there may be associated edema and/or enhancement in the surrounding brain parenchyma (see Fig. 113-2). Subsequently, the cyst fluid increases in density. As the cysticercus becomes fibrotic or collapses, neuroimaging studies reveal an area of focal enhancement, suggestive of a granuloma. Finally, the calcified stage is defined by focal areas of calcification. The calcifications are well demarcated, typically several millimeters in diameter. Edema and contrast enhancement often surround calcified lesions associated with symptoms (see Fig. 113-1).<sup>37,83</sup> Breakdown of the calcified granulomas is thought to trigger the host inflammation.

Cysticerci within the cerebral ventricles initially float in the ventricular fluid (see Fig. 113-3). They can become lodged particularly in the foramina and cause mechanical obstruction of CSF flow.<sup>84</sup> This type of obstruction is usually due to viable cysticerci.<sup>49</sup> Ependymitis and accompanying astrocytosis are associated with inflamed cysticerci or parasite remnants. The inflammation may cause the cysticerci to adhere to the ventricular walls or the inflammation may block CSF flow directly (especially in the Aqueduct of Sylvia).

Cysticerci in the basilar cisterns are associated with subarachnoid cysticercosis (see Fig. 113-4). Some of these cysticerci may enlarge to sizes up to 10 cm in diameter. These cysticerci may form clusters and without a scolex have been termed *racemose*. In fact, many of the so-called *racemose* cysticerci actually contain remnants of a scolex.

Subarachnoid NCC is usually accompanied by a prominent basilar arachnoiditis causing meningeal signs, communicating hydrocephalus, and/or vasculitis.<sup>54</sup> Hydrocephalus is thought to result from CSF outflow obstruction or blocked ventricular outflow.<sup>84</sup> Arachnoiditis often results in vasculitis, which may present as lacunar infarctions or, occasionally, as large vessel strokes.<sup>53,85</sup>

Cysticerci within the brain parenchyma typically reach a diameter of 1 to 2 cm. By contrast, cysticerci within the subarachnoid space (and particularly those in the Sylvian fissure) may expand to sizes up to 10 cm in diameter. These enlarged cysticerci may cause mass effects.<sup>52,86,87</sup> The mass effects are especially prominent when the cysticerci are inflamed either from spontaneous degeneration or after drug treatment.

## DIAGNOSIS

Diagnosis of neurocysticercosis is problematic. The main clinical presentations (e.g., seizures or hydrocephalus) are shared with a wide spectrum of other diseases. Furthermore, the location of the parasites within the central nervous system limits the usefulness of traditional parasitologic studies. Older serologic tests were limited by poor sensitivity and specificity. Immunoblot assays, with good specificity, are not widely available. Computerized neuroimaging studies (e.g., CT and MRI) have led to a dramatic increase in case identification. However, these techniques are expensive, not readily available to populations at highest risk, and may not be diagnostic.

Despite these drawbacks, neuroimaging studies are the mainstay of diagnosis.<sup>88</sup> CT scanning is more sensitive than MRI at detecting calcifications and is usually used initially.<sup>51,89</sup> MRI is better at detecting cysticerci in the ventricles and subarachnoid space.<sup>50,51,90,91</sup> MRI may also reveal the scolex, which is usually not visible on CT scans.<sup>90</sup> Either method is adequate for imaging intraparenchymal cysticerci or hydrocephalus.

Parenchymal cystic lesions are the most common neuro-radiographic manifestation of neurocysticercosis.<sup>4,51,88,92</sup> The number of cysticerci varies from one to several thousand. In India and the United States, the majority of cases of parenchymal NCC have only a single degenerating cyst.<sup>4,41</sup> By contrast, most studies from Latin America reveal multiple parasites. Whether this is due to biological differences or biases in which patients are scanned is controversial. On CT or MRI, parenchymal cysticerci appear as round cystic lesions, typically 4 to 20 mm in diameter. They are usually found in the cerebral cortex or the basal ganglia.<sup>93</sup> Cysts in the fissures are often larger, with a diameter of up to 10 cm. They may be either round or lobulated. For viable cysticerci, the cyst fluid is isodense with CSF. The cyst wall is thin (<1 mm thick) and is usually not visible. When identified, the scolex is a round or tubular nodule, 1 to 3 mm long on one side of the cyst wall. The presence of cystic lesions with a mural nodule is considered pathognomonic for cysticercosis, though this has never been rigorously tested.<sup>51,89</sup> The wall of the inflamed cyst wall is denser and may enhance with contrast (ring enhancement). The cyst fluid or surrounding tissues may also enhance. There is often edema surrounding the cysticercus, especially on T2-weighted MRI scans. Later stage cysticerci appear as focal areas of enhancement or granulomas.

Parenchymal brain calcifications are also a common CT finding in neurocysticercosis. The calcifications tend to be solid, dense, supratentorial, and 2 to 10 mm in diameter. In the absence of evidence of other illnesses, calcifications should be considered as highly suggestive of NCC. MRI scans often reveal surrounding edema and/or contrast enhancement in symptomatic cases. The latter may be associated with a residual scolex on gradient refocused echo images.<sup>38,94</sup>

Cysticerci in the ventricles are often poorly visualized by CT.<sup>50,90</sup> Most are viable cysts, with cyst fluid isodense with the cerebrospinal fluid and thin walls. The presence of ventricular cysticerci can often be inferred from distortion of the ventricular shape or the presence of obstructive hydrocephalus.<sup>50,90</sup> In contrast to CT, the increased resolution of MRI frequently allows visualization of the cyst walls and scolex.

Even though imaging studies detect most cases of neurocysticercosis, the appearance is not usually pathognomonic. Del Brutto and colleagues proposed diagnostic criteria based on neuroimaging studies, serologic tests, clinical history, and exposure.<sup>95</sup> Patients with either an absolute criterion or two major criteria alone with two minor or epidemiologic criteria were considered to have a definite diagnosis. One major criterion plus and two other criteria or three minor criteria plus exposure were considered to establish a probable diagnosis (Box 113-1).

Absolute diagnostic criteria for NCC include identification of the parasite by visualization or histology or pathognomonic neuroimaging results.<sup>95</sup> Traditionally, parasitologic diagnoses have depended on demonstration of the infecting parasite, but biopsy or autopsy material demonstrating *T. solium*

**Box 113-1** Diagnostic Criteria for Neurocysticercosis**Absolute Criteria**

Histologic demonstration of the parasite from biopsy of a brain or spinal cord lesion  
 Cystic lesions showing the scolex on CT or MRI  
 Direct visualization of subretinal parasites by fundoscopic examination

**Major Criteria**

Lesions highly suggestive of neurocysticercosis on neuroimaging studies  
 Positive serum immunoblot for the detection of anticysticercal antibodies  
 Resolution of intracranial cystic lesions after therapy with albendazole or praziquantal  
 Spontaneous resolution of small single enhancing lesions

**Minor Criteria**

Lesions compatible with neurocysticercosis on neuroimaging studies  
 Clinical manifestations suggestive of neurocysticercosis  
 Positive CSF ELISA for detection of anticysticercal antibodies or cysticercal antigens  
 Cysticercosis outside the central nervous system  
 Epidemiologic criteria  
 Evidence of a household contact with *T. solium* infection  
 History of frequent travel to disease-endemic areas  
 Individuals coming from or living in an area where cysticercosis is endemic

One major criterion and two other criteria or three minor criteria plus exposure were considered to establish a probable diagnosis.  
 From Del Brutto OH, Rajshekhar V, White AC Jr, et al: Proposed diagnostic criteria for neurocysticercosis. *Neurology* 57:177–183, 2001.

parasites are only available in a minority of cases. Parasites can occasionally be visualized directly in the eye. Neuroimaging studies revealing a cystic lesion with an associated scolex (demonstrated as a 1–3 mm mural nodule) are thought to be pathognomonic for cysticercosis.<sup>51,89</sup>

Neuroimaging studies highly suggestive of NCC were considered a major diagnostic criteria. These included cystic lesions, single or multiple ringlike or nodular enhancing lesions, and typical parenchymal brain calcifications. Ring or nodular enhancing lesions are also highly suggestive of neurocysticercosis, but tuberculomas, brain abscesses, and tumors can cause similar lesions. Cysticercal lesions are usually smaller than 20 mm in diameter and rarely cause midline shift.<sup>25</sup>

Rajshekhar and colleagues developed clinical and radiologic criteria for cysticercosis among patients who presented with seizures and single enhancing lesions.<sup>25</sup> The combination of a single, round, enhancing lesion, less than 20 mm in diameter, with no midline shift, in patients without increased intracranial pressure, focal neurologic deficits, or evidence of systemic disease was highly suggestive of NCC. These criteria were prospectively studied in 400 patients in India with a high sensitivity and specificity.<sup>25</sup> Resolution of the lesion spontaneously or after anticysticercal therapy or precipitation of symptoms by antiparasitic drugs are also supportive of the diagnosis.<sup>96</sup> All of these are major diagnostic criteria.<sup>95</sup>

Serodiagnosis is helpful in many parasitic diseases, but has proven problematic in the diagnosis of cysticercosis due to cross-reactions to other parasites and nonspecific binding. In general, assays employing unfractionated antigen have poor sensitivity and specificity.<sup>97,98</sup> The enzyme-linked immunotransfer blot (EITB) is an immunoblot assay employing semi-purified membrane antigens.<sup>99</sup> Binding to any one of seven bands is considered positive. Studies have confirmed nearly 100% specificity, but the sensitivity is limited in subjects with either a single lesion or with only calcified lesions.<sup>11,98,100,101</sup> Interestingly, performance data suggests that the predictive value of the EITB assay for neurocysticercosis is better with serum than with CSF.<sup>100</sup> Other serologic tests are less accurate and are not considered major diagnostic criteria. Assays to detect parasite antigens may prove to be an important diagnostic tool.<sup>102–107</sup> Currently, a number of different antigen detection tests are being developed.

Minor criteria include: (1) lesions on neuroimaging studies that might be NCC, but are less suggestive (e.g., isolated basilar meningitis, hydrocephalus, or filling defects in the spinal subarachnoid space without discrete cysticerci); (2) symptoms suggestive of NCC (e.g., seizures or hydrocephalus); and (3) serologic tests for cysticercosis other than the EITB, and cysticercosis outside the nervous system (e.g., cigar-shaped muscle calcifications or subcutaneous nodules). Epidemiologic criteria include residence or prolonged visits to endemic areas or contact with a tapeworm carrier.

**TREATMENT AND PROGNOSIS**

Antiepileptic therapy, antiparasitic drugs, anti-inflammatory drugs, and surgical therapy are all important in the management of some neurocysticercosis patients. A key to management is that therapy should be individualized based on the pathogenesis of different forms of disease.

**Symptomatic Therapy**

Symptomatic therapy plays a key role in the management of NCC. Most fatalities are associated with failure to provide effective therapy for complications such as raised intracranial pressure or seizures. The key component in treatment of seizures should be effective antiepileptic drugs. Most seizures can be controlled with any of a number of antiepileptic drugs. A single first-line antiepileptic drug such as phenytoin or carbamazepine can successfully control seizures in most patients.<sup>33,45,108</sup> Breakthrough seizures often reflect poor adherence, subtherapeutic drug levels, or coexisting conditions (e.g., alcohol abuse).<sup>46</sup> Among patients in whom neuroimaging studies normalize and seizures are controlled, antiepileptic treatment may eventually be tapered,<sup>33,44–46</sup> although seizures may recur in 20% to 40% of patients. In some studies, the presence of residual calcifications is a marker for high risk of recurrent seizures and is thought to be an indication for continuous antiepileptic.<sup>35</sup>

Hydrocephalus is primarily treated surgically. Obstructive hydrocephalus should be treated acutely by CSF diversion procedures such as ventriculoperitoneal shunting.<sup>49</sup> In the past, there was a high rate of shunt failure, in part due to aspiration of the cysticerci into the shunt. Recent studies have

demonstrated that antiparasitic drugs and/or treatment with corticosteroids decreases the rate of shunt failure.<sup>42,49,109–112</sup>

### Corticosteroids

Corticosteroids are used in neurocysticercosis to control inflammation and are a key component of therapy for severe forms of NCC, including cysticercal encephalitis, subarachnoid neurocysticercosis, and spinal intramedullary cysticercosis. For patients with NCC in the subarachnoid space, meningitis, vasculitis with stroke, and communicating hydrocephalus can result from the host inflammatory response and accompanying arachnoiditis. Corticosteroid therapy is an essential component in these cases. There are few data available on the optimal dose or duration of therapy. For severe disease, high doses (e.g., 1 mg/kg/d of prednisone or 0.5 mg/kg/d of dexamethasone) are often used initially. Lower doses have been used along with antiparasitic drugs to ameliorate the inflammatory reaction to the dying parasite. One randomized trial suggested that treatment with a short course of prednisolone (1 mg/kg/d for 10 days) led to a marked reduction in seizures and more rapid resolution in patients with single enhancing lesions.<sup>113</sup>

### Antiparasitic Drugs

The role of antiparasitic drugs in the treatment of NCC has been controversial. Before CT and MRI scanning were available, the spectrum of cases diagnosed was weighted toward more severe disease. The development and dissemination of CT and MRI led to diagnosis of milder cases. Praziquantel and later albendazole were recognized as antiparasitic agents that could kill the parasites. In Latin America, initial uncontrolled trials of antiparasitic drugs were associated with resolution of neuroimaging abnormalities and improved prognosis, which was attributed to antiparasitic drug therapy.<sup>114</sup> In the United States, neuroimaging studies were available before antiparasitic drugs became available, and clinicians recognized that many cases (especially patients with single enhancing lesions) resolved spontaneously without antiparasitic therapy.<sup>81,108</sup> When antiparasitic drugs became available, reports noted worsening symptoms with treatment.<sup>115</sup> The first randomized, controlled trials were published in the 1990s and consensus on optimal management is only now emerging.<sup>116</sup>

Praziquantel was the first antiparasitic drug reported effective in neurocysticercosis. Praziquantel is absorbed well after oral administration, but has extensive first-pass metabolism, which is augmented by antiepileptic drugs (carbamazepine, phenytoin, and probably phenobarbital) as well as by corticosteroids.<sup>117,118</sup> This induction can be inhibited by cimetidine (e.g., 400 mg PO tid). Coadministration increases levels of praziquantel, but the effect of the increased drug levels on efficacy are unproven.<sup>119–122</sup> Initial dose ranging studies demonstrated greater effect at doses greater than or equal to 50 mg/kg/d in 3 daily doses for 14 days. Subsequent studies demonstrated that doses as high as 100 mg/kg/d could be given safely.<sup>123</sup> Studies with praziquantel in parenchymal NCC given in 3 doses of 25 mg/kg separated by only 2 hours along with cimetidine suggest similar efficacy with longer courses of therapy.<sup>122,124,125</sup> Adverse effects including worsening neurologic function (e.g., headaches, dizziness, seizures, increased intracranial pressure) are due to the host inflammatory response to the dying parasite.

Some observers recommended use of corticosteroids along with antiparasitic drugs to decrease side effects,<sup>115</sup> but routine use of corticosteroids could potentially decrease efficacy of praziquantel by affecting serum levels.

Albendazole is a benzimidazole anthelmintic agent with broad-spectrum activity. Albendazole is usually used at doses of 15 mg/kg/d in 2 daily doses. Side effects include mild gastrointestinal problems and inflammatory responses to the parasites. Imaging studies demonstrated resolution of parenchymal cysticerci as good or better than those noted with praziquantel.<sup>126,127</sup> Controlled trials in parenchymal NCC showed no difference in neuroradiologic resolution with treatment for 7 days versus longer courses.<sup>127–129</sup> Albendazole was subsequently studied in cases of extraparenchymal disease and was associated with improvement.<sup>52,109,112,130–132</sup> However, none of these trials were controlled, due to concerns about disease progression.

Seven well-controlled studies of antiparasitic drugs have been performed in different forms of parenchymal neurocysticercosis.<sup>46,133–138</sup> Overall, the studies demonstrate that patients with parenchymal NCC have a more rapid radiologic response when treated with antiparasitic drugs both in cystic lesions as well as in degenerative (enhancing) lesions.

### Active Parenchymal NCC with Cystic Lesions

In parenchymal cystic NCC, the clinical response is generally favorable. A recent randomized trial compared albendazole plus corticosteroids to symptomatic therapy alone and found fewer seizures in the treatment group, although the proportions of patients with at least one seizure relapse were similar.<sup>38</sup> While imaging studies will eventually normalize with or without antiparasitic drugs, Garcia and colleagues clearly demonstrated that spontaneous resolution of the cystic lesions was prolonged (>6 months) unless patients were treated with antiparasitic drugs.<sup>108,133–137</sup>

Patients present with seizures at the time of inflammation around the cyst. Thus, seizures tend to cluster in the initial weeks or months.<sup>45,46</sup> On the other hand, seizures are more common while there is residual parasite material present<sup>45,46</sup> and most studies demonstrate more rapid normalization with antiparasitic therapy.<sup>46,134</sup> The prognosis is thought to be worse when there are multiple lesions.<sup>116,133</sup> The resolution of viable and inflamed parasites may not be synchronized. Thus, most experts now argue that antiparasitic drugs improve the outcome in those with viable cysticerci and in those with multiple lesions.<sup>43,46,116,133</sup>

### Active Parenchymal NCC with Only Enhancing Lesions

In parenchymal NCC with only enhancing lesions, the clinical response is generally favorable with or without antiparasitic therapy. Recent trials comparing albendazole plus corticosteroids<sup>138</sup> or just prednisolone<sup>113</sup> to symptomatic therapy alone in patients with single enhancing lesions demonstrated more rapid radiographic resolution and fewer seizures in follow-up in the treatment group. While there is no consensus, most experts agree that the prognosis for patients with single inflamed lesions is quite favorable with only symptomatic therapy.<sup>108,116,133,139</sup> However, there may be

some clinical benefit of a short course of corticosteroids with or without albendazole.<sup>113,138</sup>

In cases with numerous inflamed lesions with associated diffuse cerebral edema (cysticercal encephalitis), antiparasitic drugs are contraindicated.<sup>116</sup> Instead, treatment should focus on management of cerebral edema with high-dose corticosteroids (e.g., dexamethasone).

### Inactive Parenchymal NCC

Antiparasitic drugs are not recommended in inactive infection, since there are no signs of viable parasites. Patients with inactive parenchymal NCC typically present with seizures. Seizures are clustered near the time of diagnosis, but they reoccur years later.<sup>35,44,45</sup> Thus, these patients require chronic antiepileptic therapy. If patients maintain therapeutic levels of the drugs, the risk of recurrent seizures is very low.<sup>33</sup> On imaging studies, some patients will show contrast enhancement or edema around established calcified lesions.<sup>37–39</sup> Whether or not these patients would benefit from anti-inflammatory treatment is unclear.

### Ventricular NCC

Some patients have hydrocephalus related to scarring from prior infection (e.g., aqueductal stenosis).<sup>86</sup> In this case, hydrocephalus can be corrected by ventriculoperitoneal shunting without the need for antiparasitic drugs. Patients with active ventricular neurocysticercosis usually present with obstructive hydrocephalus. Initial management should focus on relieving intracranial hypertension, reversing hydrocephalus, reducing the risk for recurrence, and minimizing treatment-associated morbidity.<sup>140</sup> In the past, removal of the cysticercus from the ventricle via an open craniotomy was the main approach. Since open brain surgery is associated with significant morbidity, alternative approaches have been tried. Recent studies have demonstrated that cysticerci can usually be removed by endoscopic surgery. When feasible, endoscopic surgery is the preferred approach, but patients should be selected carefully.<sup>140–146</sup> Lateral and 3rd ventricular cysts can be removed with rigid endoscopes and the 4th ventricle can be approached with flexible endoscopes. Patients with significant ependymal enhancement have not been effectively managed surgically due to adherence of the cysticerci to the ependyma. These patients may not be good candidates for endoscopic removal.<sup>140</sup>

An alternative approach, especially in the setting of acute decompensation, is placement of a ventriculoperitoneal shunt. Shunting is associated with a lower perioperative mortality rate than seen with an open craniotomy.<sup>87</sup> Up to 75% of shunts malfunction requiring shunt revision or replacement if no other treatment is given. Recent studies have demonstrated that requirement for shunt revision are infrequent among patients who are also treated with antiparasitic drugs.<sup>41,49,109,110,112</sup> Similarly, corticosteroids may decrease the risk of shunt obstruction.<sup>111</sup>

### Subarachnoid NCC and Giant Cysticerci

Subarachnoid cysticercosis is a rare form associated with a poor prognosis. In one series, patients treated with only CSF

diversion were noted to have a 50% mortality rate.<sup>147</sup> Complications include mass effect, communicating hydrocephalus, vasculitis with strokes, and basilar meningitis.<sup>52,54,86</sup> The basilar arachnoiditis appears to play an important role in the pathogenesis.

There are no controlled trials of management of subarachnoid NCC. Case series in which patients were treated with antiparasitic drugs, corticosteroids, and shunting for hydrocephalus have demonstrated a markedly improved prognosis compared to older studies.<sup>27,52,131,132</sup> Thus, most experts consider subarachnoid NCC an indication for antiparasitic therapy.<sup>116</sup> The optimal doses and duration of therapy have not been defined, but patients appear to require prolonged or repeated courses of antiparasitic drugs. Patients should be treated with albendazole 15 mg/kg/d for at least 28 days. They should also receive high doses of corticosteroids (e.g., prednisone 60 mg per day).

### Other Forms of Neurocysticercosis

Spinal NCC can be subarachnoid or intramedullary. There is only anecdotal evidence on the effectiveness of any therapies. Intramedullary should usually be approached surgically due to the risk of paralysis from cord swelling.<sup>116</sup> Spinal subarachnoid cysticerci, however, may respond to antiparasitic drugs.<sup>27</sup> Ocular disease may also respond to antiparasitic treatment, but the standard therapy is still surgical removal.<sup>116</sup>

### PREVENTION

Cysticercosis was hyperendemic in Europe in the 19th century. However, transmission was eliminated by improved sanitation, better animal husbandry, and meat inspection.<sup>148,149</sup> Porcine cysticercosis can be prevented by confining pigs and not allowing them access to human fecal material.<sup>150</sup> However, in most areas pigs function as scavengers cleaning up waste. By contrast, confined pigs must be fed, adding expenses to the cost of raising them. This economic pressure is a major barrier to corralling the pigs as a method of control. Human infection with adult tapeworms can also be prevented by destruction, freezing, or adequate cooking of meaty pork. Meat inspection has been unsuccessful in areas where pigs are raised by peasant farmers.<sup>151</sup> Treatment of human tapeworm carriers could potentially eliminate the disease, but current detection methods are suboptimal. Mass chemotherapy of endemic populations results in significant decreases in human taeniasis and porcine cysticercosis, but the effects are of short duration.<sup>148,152,153</sup> Development of an effective vaccine against cysticercosis may provide the best potential tool toward the eradication of the disease. A recombinant vaccine has been developed for *Taenia ovis* that can provide nearly complete protection. This vaccine is currently commercially available in several countries. *T. solium* homologues have been cloned and initial studies suggest efficacy.<sup>154</sup>

### Coenurosis

Human infection with the larval form of the canine tapeworm *Taenia multiceps* (*Multiceps multiceps*) is termed *coenurosis* and is reported from tropical and subtropical areas of the world.

Rarely, human disease may be caused by zoonotic infection with *Taenia serialis*.

### AGENT

The definitive hosts are dogs, wolves, foxes, and coyotes, where adult *T. multiceps* or *T. serialis* are found in the small intestines.<sup>155</sup> The gravid proglottids passed in the feces of the canid hosts disintegrate and release eggs that are ingested by intermediate hosts including rabbits and rodents. The larval stage of *T. multiceps* usually develops in herbivores such as sheep, goats, or horses, whereas the larval stage of *T. serialis* is usually found in rabbits and squirrels. Humans may also serve as an accidental intermediate host as a consequence of ingestion of eggs released by proglottids in dog feces. As in hydatid disease, the oncospheres eventually lodge in various tissues of the body, typically the brain and spinal cord of herbivores. The cyst or bladder, about the size of a hen's egg, eventually develops. The inner membrane of the bladder develops multiple protoscolices and floating in the bladder fluid are numerous small bladders containing protoscolices or metacestodes. External bladders are also formed that remain attached by long stalks to the main bladder.

### EPIDEMIOLOGY

The majority of human cases have been reported from Africa, specifically Kenya, Uganda, Nigeria, and South Africa.<sup>156–158</sup>

Human cases have also been reported from the United Kingdom, France, and North America.<sup>159</sup> Subcutaneous, ocular, muscle, and CNS cysts have been commonly described, although it is unclear if all cases were due to *T. multiceps*.

### DISEASE

Human coenurosis usually involves the CNS, where it presents as a cyst and acts as a space-occupying mass causing pressure necrosis as it enlarges. Intracerebral cysts may cause seizures or other localizing signs and symptoms and can be confused with neurocysticercosis and echinococcosis. Intraparenchymal lesions of the spinal cord have been reported. This infection may be associated with meningitis, arteritis, arachnoiditis, ependymitis, and involvement of the eye. Subcutaneous and intramuscular cysts are reported most commonly in Africa and involve the intercostal area and anterior abdominal wall. Allergic symptoms, such as recurrent urticaria, fever, and night sweats, have also been reported.

### DIAGNOSIS

Presumptive diagnosis by MRI or CT scan, as well as ultrasound, has been helpful but not definitive.<sup>159,160</sup> The definitive diagnosis is dependent on surgical excision and pathologic identification (Fig. 113-6). Fine-needle aspiration of a cyst has been reported to yield a diagnosis.<sup>159</sup> There is no reliable serologic test for this disease.

**FIGURE 113-6** A and B, Pathologic images of coenurosis caused by *Taenia multiceps*.

## TREATMENT AND PREVENTION

Surgical intervention has been the mainstay of therapy.<sup>161</sup> There are no reliable data on the use of praziquantel or albendazole in this disease. Elimination of adult worms with praziquantel may reduce transmission from dogs to humans.

# Echinococcosis

PETER M. SCHANTZ

PETER KERN

ENRICO BRUNETTI

## INTRODUCTION

Echinococcosis is an infection caused by cestodes of the genus *Echinococcus* (Rudolphi, 1801) (Cestoda: Taeniidae), the life cycles of which involve two mammalian hosts. The definitive hosts are carnivores, in which adult worms are present in the intestines. *Echinococcus* eggs, passed in feces of definitive hosts, hatch when ingested by suitable intermediate hosts, including humans, and the liberated embryos migrate to parenteral sites and develop into the metacestode (larval) forms. Under natural conditions, transmission of *Echinococcus* spp. from intermediate to definitive hosts is the result of predator-prey relationships existing between hosts; however, transmission in synanthropic cycles is considerably modified by human behavioral factors. The larval forms are referred to as hydatid cysts, and the diseases caused by them are commonly referred to as cystic, alveolar, or polycystic hydatid disease or echinococcosis.

Historical and current aspects of the controversy concerning speciation within the genus *Echinococcus* have been reviewed by Thompson and McManus.<sup>1,2</sup> Until recently, the genus *Echinococcus* contained four generally accepted species: *Echinococcus granulosus* (Batsch, 1786), *Echinococcus multilocularis* (Leuckart, 1863), *Echinococcus oligarthrus* (Diesing, 1863), and *Echinococcus vogeli* (Rausch and Bernstein, 1972) are morphologically distinct in both adult and larval stages (Table 114-1). A fifth species, *Echinococcus shiquicus*, has recently been described.<sup>3</sup> One of these species, *E. granulosus*, is made up of a number of biologically and genetically distinct entities whose taxonomic positions are in states of flux. These variants are separated ecologically, although not necessarily geographically, by the nature of their respective unique host assemblages. They have been referred to as strains or subspecies<sup>2</sup>; however, recent proposals have elevated several of them to separate species status, some of them reflecting much earlier proposals based on morphologic characteristics and host specificities (see Table 114-1).

Classic cystic echinococcosis (CE) is caused by *E. granulosus*. Increasing knowledge of genetic diversity within populations previously considered *E. granulosus* has revealed that cestodes causing "cystic echinococcosis" are actually a complex of related species (discussed later). These variant species are adapted to dogs and a wide variety of domestic and sylvatic animal intermediate hosts. CE exists throughout the world; in many regions, it is a major public health and economic problem.

Alveolar echinococcosis (AE) is caused by *E. multilocularis*, whose final and intermediate hosts are foxes and their rodent prey, respectively. Human infection caused by this species is one of the most lethal parasitic infections and is characterized by a tumor-like, infiltrative growth. The infection is widely distributed in the Northern Hemisphere, but the greater host specificity of *E. multilocularis* and its usual restriction to sylvatic animal hosts reduce potential human exposure.

Polycystic echinococcosis (PE) is caused by *E. vogeli* and, less commonly, *E. oligarthrus*, the life cycles of which are limited to sylvatic animals. The definitive host of *E. vogeli* is a wild canid, whereas *E. oligarthrus* utilizes wild felids as definite hosts. Both species use a variety of rodents as intermediate hosts. Infection by these cestodes has been reported from Central and South America.

The newly described *E. shiquicus*, discovered parasitizing the intestine of the Tibetan fox (*Vulpes ferrilata*) on the eastern Tibetan plateau in China, is distinct morphologically and genotypically from previously described species. Molecular phylogenetic analysis of mitochondrial genes indicates that *E. shiquicus* is the most primitive of the recognized species in the genus, which may imply a Eurasian origin for *Echinococcus* spp.<sup>3</sup> The larval stage has been found parasitizing the black-lipped pika (*Ochotona curzoniae*). Nothing is known of potential infectivity for humans.

Current biological, epidemiologic, and clinical aspects of the echinococcoses were reviewed by international consultants of the World Health Organization's Informal Working Group on Echinococcosis (WHO/IWGE).<sup>4</sup>

## ■ Cystic Echinococcosis (*Echinococcus granulosus* and Related Species)

### AGENT

*Echinococcus granulosus* was the first *Echinococcus* sp. to be described, its larval form having been characterized in the writings of Hippocrates. For many years, considerable morphologic and biologic variability has been noted between populations of *E. granulosus* in different geographic regions and in different host assemblages; described differences have included features such as morphology, biochemistry, physiology, pathogenicity, developmental patterns, and infectivity to humans and domestic animals.<sup>1,2</sup> Whereas adults consistently infect canids, metacestodes from different "strains" or genotypic variant populations appear to be adapted to distinct species of domestic and wild herbivorous hosts, including sheep, cattle, pigs, horses, and wild cervids. However, the host specificities of a given variant population vary enormously. Molecular characterization has revealed that the genetic differences between what were perceived to be host-adapted strains of *E. granulosus* are conserved and occur consistently in isolates derived from different species of intermediate hosts throughout the world.<sup>1,2</sup> This has been demonstrated for the sheep, horse, cattle, pig, and camel genotypes in molecular epidemiological studies in Europe, Iran, Africa, and South America.<sup>5</sup>

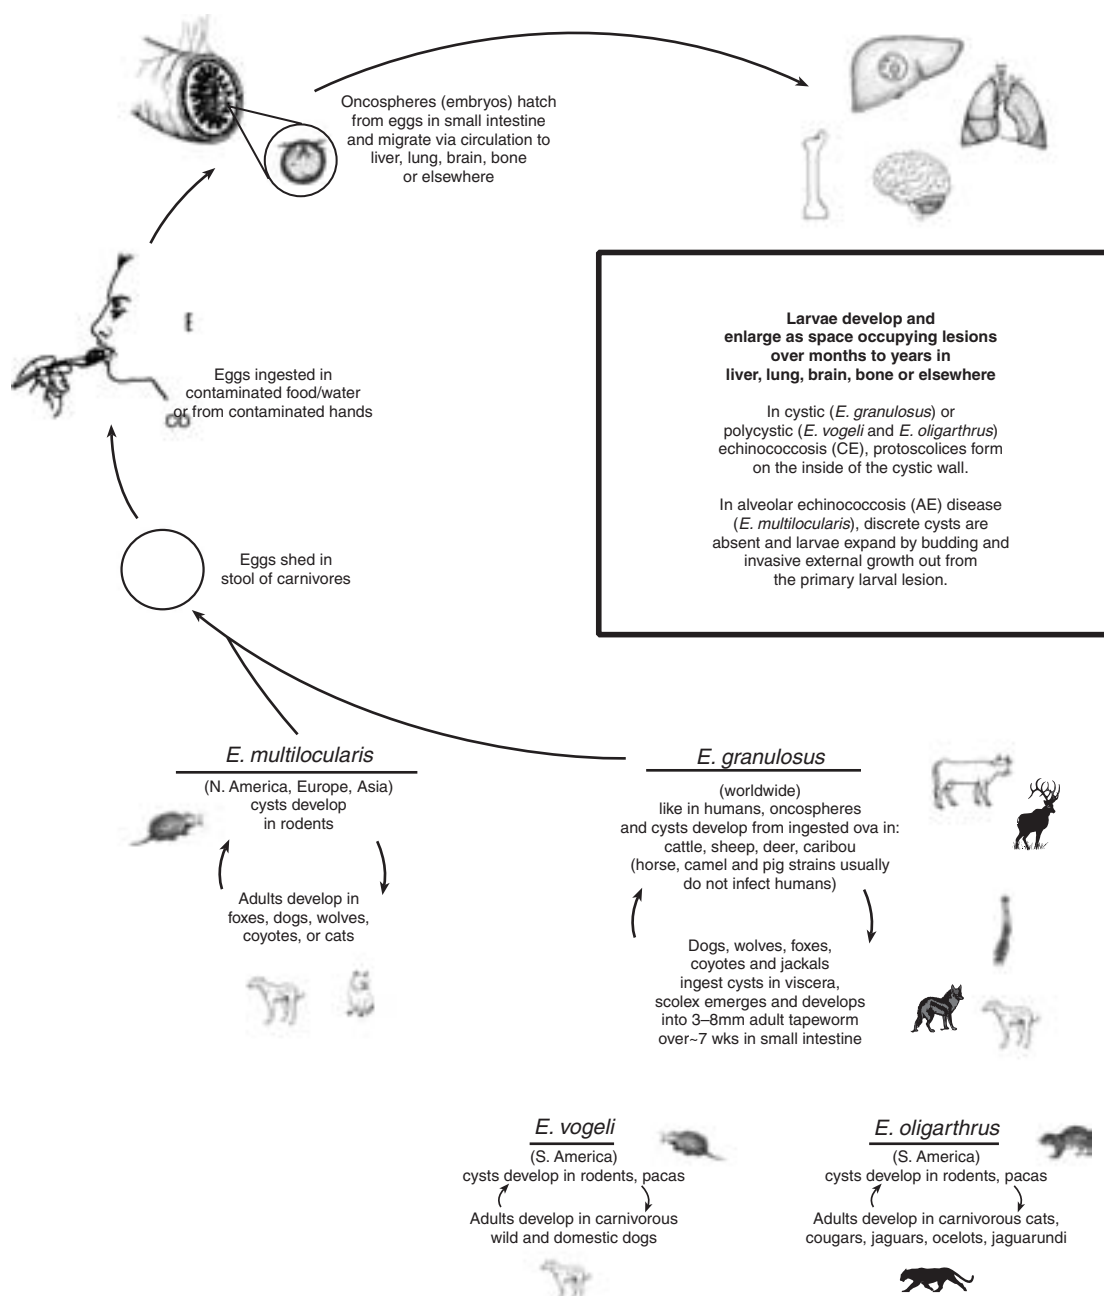

**Table 114-1** Characteristics of Hosts and Known Geographic Distribution of Recognized and Proposed Species and Strains in the Genus *Echinococcus*.

Species Strain/Isolate (Genotype)	Known Intermediate Hosts	Infective to Humans?	Known Definitive Hosts	Probable Geographical Distribution	Proposed Taxonomic Designation
<i>Echinococcus granulosus</i>					
Sheep strain (G1)	Sheep, cattle, pigs, camels, goats, macropods	Yes	Dog, fox, dingo, jackal, hyena	Australian mainland, Europe, USA, New Zealand, Africa, China, Middle East, South America, Russian Federation	<i>E. granulosus</i>
Tasmanian sheep strain (G2)	Sheep, cattle?	Yes	Dog, fox	Tasmania, Argentina	<i>E. granulosus</i>
Buffalo strain (G3)	Buffalo, cattle?	?	Dog, fox?	Asia	<i>E. granulosus</i>
Horse strain (G4)	Horses and other equines	No	Dog	Europe, Middle East, South Africa	<i>Echinococcus equinus</i>
Cattle strain (G5)	Cattle	Yes	Dog	Europe, South Africa, India, Nepal, Russian Federation, South America?	<i>Echinococcus ortleppi</i>
Camel strain (G6)	Camels, goats, cattle?	Yes	Dog	Middle East, Africa, China, Argentina	<i>E. granulosus?</i>
Pig strain (G7)	Pigs	Yes	Dog	Europe, Russian Federation, South America	<i>Echinococcus intermedius</i>
Cervid strain (G8)	Moose, caribou, reindeer	Yes	Wolf, coyote, dog	North America, Eurasia	<i>E. granulosus</i>
Fennoscandinavian cervid strain (G10)	Reindeer, moose?	?	Wolf, dog	Eurasia	<i>E. granulosus?</i>
Lion strain	Zebra, wildebeest, warthog, bushpig, buffalo, various antelope, giraffe? Hippopotamus?	?	Lion	Africa	<i>E. granulosus?</i>
<i>Echinococcus multilocularis</i>					
European isolate	Rodents, domestic and wild pig, dog, monkey	Yes	Fox, dog, cat, wolf raccoon-dog	Europe, China?	<i>E. multilocularis</i>
Alaskan isolate	Rodents	Yes	Fox, dog, cat	Alaska	<i>E. multilocularis</i>
North American isolate	Rodents	Yes	Fox, dog, cat, coyote	North America	<i>E. multilocularis</i>
Hokkaido isolate	Rodents, pig, monkey, horse	Yes	Fox, dog, cat, raccoon-dog	Japan	<i>E. multilocularis</i>
<i>Echinococcus vogeli</i>					
None reported	Rodents	Yes	Bush dog	Central and South America	<i>E. vogeli</i>
<i>Echinococcus oligarthrus</i>					
None reported	Rodents	Yes	Wild felids	Central and South America	<i>E. oligarthrus</i>
<i>Echinococcus shiquicus</i>					
None reported	Rodents, lagomorphs?	?	Tibetan fox	Tibetan Plateau (China)	<i>E. shiquicus</i>

Modified from Thompson RCA, McManus DP: Toward a revised nomenclature of *Echinococcus*. Trends Parasitol 18:452–457, 2002; and McManus DP, Thompson RCA: Molecular epidemiology of cystic echinococcosis. Parasitology 127:S37–S51, 2003.

Current data, based on genome patterns, generally support previous characterizations based on morphologic and biologic criteria: At least 10 genetically distinct populations exist within the complex until recently denoted *E. granulosus*<sup>1,2</sup> (Fig. 114-1; see Table 114-1). Probes characterizing the mitochondrial and genomic DNA of the variant populations provide reliable genetic markers to distinguish them.<sup>2</sup> The “sheep” genotype (G1) is maintained in life cycles involving dogs and sheep; it also sometimes infects humans, cattle, goats, buffalo, camels, pigs, macropods (intermediate hosts), and foxes and some other canids (definitive hosts), although development and maturation in some of these hosts are significantly impaired

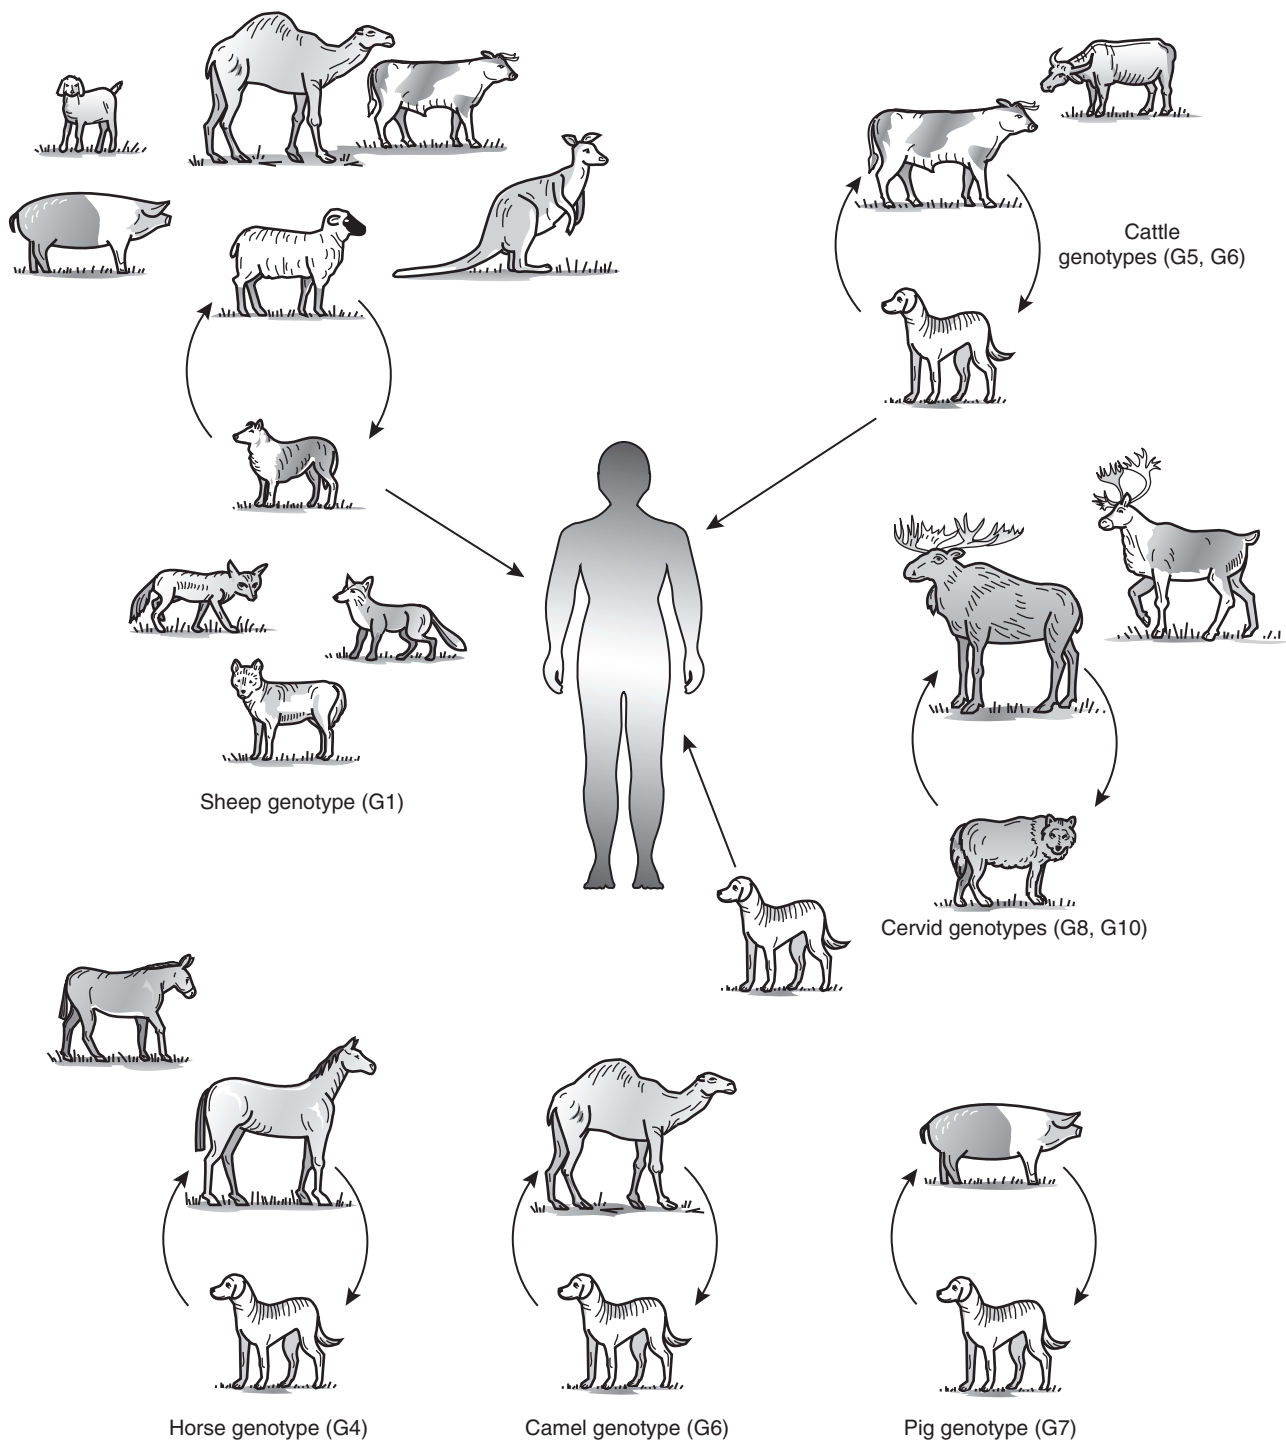

in comparison to those in sheep and dogs. The genetic structure of this strain is highly uniform throughout its nearly cosmopolitan geographic distribution; however, a second sheep genotype (G2), slightly different from the common sheep strain in mitochondrial DNA sequences, has been identified in Tasmania. This isolate is also morphologically distinct and has a significantly shortened prepatent period in dogs than the common sheep strain. The “horse” genotype (G4) is adapted to horses, donkeys, and dogs throughout the United Kingdom, areas of Europe, the Middle East, and possibly South Africa and New Zealand; no human infections with this genotype have been identified. The “cattle” genotype (G5) occurs in cattle

and dogs in western Europe and in buffalo in Sri Lanka and India. The cysts occur mainly in the lungs of cattle and buffalo and, in contrast to those caused by infection of cattle with the sheep genotype (G1), are large and highly fertile. The “camel” genotype (G6) is found in areas of the Middle East and North Africa in cycles involving camels and dogs. The “pig” genotype (G7), adapted to pigs and dogs, has been characterized from isolates in eastern Europe, but it may occur much more widely; human infections with this genotype are reported from Poland.<sup>6</sup> The “cervid” or northern sylvatic genotype (G10) is maintained in cycles involving wolves and dogs and moose, caribou, and other cervids throughout northern North America and does not readily infect domestic ungulates.<sup>7</sup> Human infection with this strain is characterized by predominantly pulmonary localization, slower and more benign growth,

and less frequent occurrence of clinical complications than reported for other forms. A distinct genotypic *Echinococcus* sp. (G10) appears to be the variant infecting reindeer and moose in Fennoscandia.<sup>8</sup> A limited number of isolates from humans have been typed as the cattle strain and the pig strain.<sup>1,2,6</sup> An increasing amount of data support long-held speculations that the horse strain is noninfective to humans.

It is likely that the *Echinococcus* speciation question will be debated for some time and clarified as additional information is presented. At this time, it is important to recognize that important biologic differences exist between populations currently identified in many texts as *E. granulosus*, the causative agent of CE, and that these may account for local differences in patterns of transmission and clinical and public health significance of the disease. The great majority of *E. granulosus*

**FIGURE 114-1** Life cycle patterns of principal genotypic variants of the *Echinococcus granulosus* complex and infectivity to humans. Curved arrows designate principal and alternative definitive and intermediate hosts. Straight arrows designate those variants known to infect humans. (See Table 114-1 for complete listing.) (Modified from Schantz PM, Chai J, Craig PS, et al: Epidemiology and control. In Thompson RCA, Lymbery AJ, [eds]: Echinococcosis and Hydatid Disease. London, CAB, 1995.)

isolates from human patients thus far characterized by genotype have been of the sheep genotype (G1), and this and the worldwide epidemiologic association of high endemicity with sheep raising confirm the paramount public health importance of the sheep genotype.

Comparative details of maturation and growth rates of most of the *E. granulosus* genotypic variants are not available,

and the following description applies primarily to genotype G1 in sheep and canid hosts. The adult intestinal forms of *E. granulosus* genotypic variants are small tapeworms approximately 3 to 7 mm in length when fully mature; they attach firmly to the small intestine of the canine host (Fig. 114-2). Following infection by ingestion of protoscolices originating from fertile hydatid cysts, sexual maturity of adult-stage

**FIGURE 114-2** Comparative morphology of adult-stage *Echinococcus* species. (From Rausch RL, Bernstein JJ: *Echinococcus vogeli* sp.n [Cestodea: Taeniidae] from the bush dog *Speothos venaticus* [Lund]. *Tropenmed Parasitol* 23:25, 1972.)

***E. GRANULOSUS*    *E. MULTILOCULARIS*    *E. VOGELI*    *E. OLIGARTHUS***

tapeworms is reached within 4 to 7 weeks. Development from ovum to the oncosphere or hexacanth embryo takes place in utero in the adult *Echinococcus*. The oncosphere measures approximately 0.018 mm and is bilaterally symmetrical, possessing three pairs of hooks (hexacanth), muscle fibers, and glands, which aid it in penetration and locomotion within the intermediate host. The oncosphere and its surrounding membranes (0.030 to 0.036 mm in diameter) are often referred to as the cestode egg. Eggs are shed with the feces into the external environment, and when ingested by a suitable intermediate host, the oncospheres hatch and become activated. Lytic secretions may facilitate the passage of the motile oncosphere through the intestinal mucosa and into the host's circulatory system (via venous and lymphatic pathways). They are distributed to other sites via the host's circulatory system, where postoncospherical development continues. Within a few days after the oncospheres reach their preferred site, cystic development begins. This process involves degeneration of the oncospherical stage and emergence of the vesicular metacystode stage, which grows expansively by concentric enlargement. In general, hydatid cysts increase in diameter from 1 to 5 cm each year, depending on unknown factors. Protoscolex formation occurs as early as 4 months in white mice, but it may require more than 1 year in sheep and other intermediate hosts.

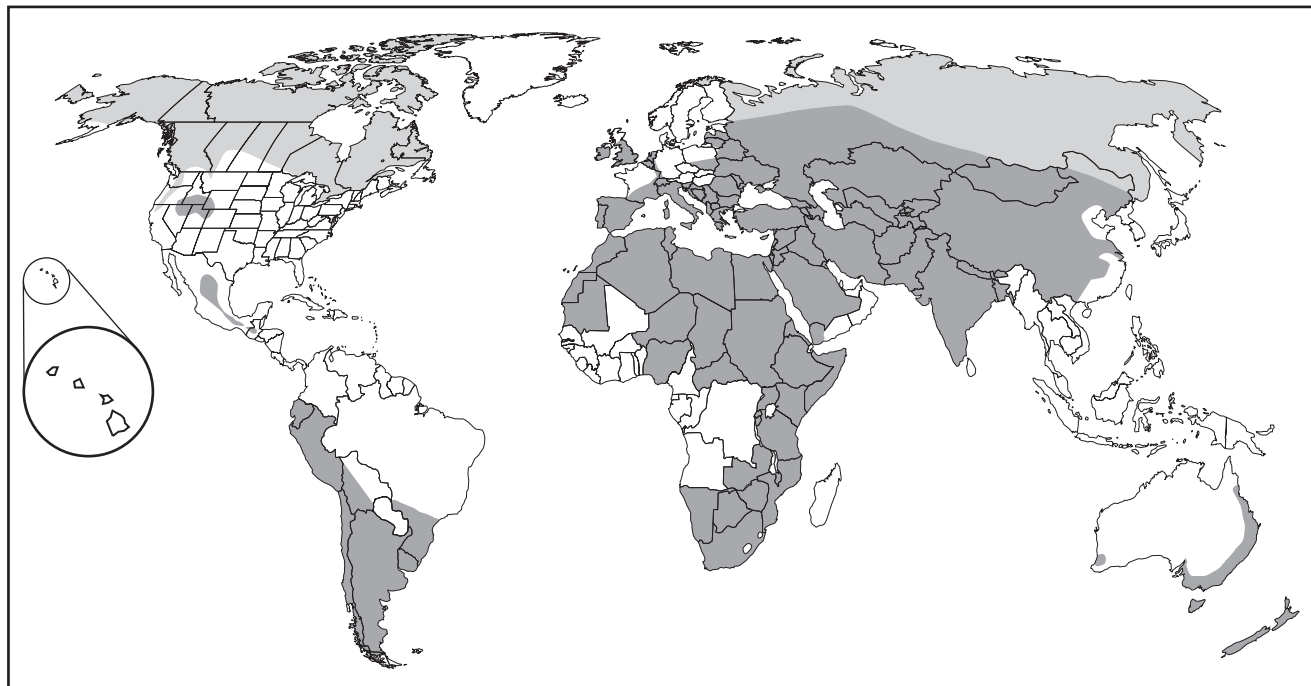

The fully developed metacystode (hydatid or hydatid cyst) of *E. granulosus* is typically fluid-filled and unilocular, but multiple chambers may also occur. Structurally, the cyst consists of an inner germinative layer of cells supported externally by a characteristic acidophilic-staining, acellular, laminated membrane of variable thickness (Fig. 114-3). Cytoplasmic extensions of the germinative layer unite to form a syncytium, which is differentiated into numerous microtriches. The microtriches project peripherally into the laminar layer toward the host tissues surrounding the cyst. Surrounding the parasitic cyst is a host-produced, granulomatous, adventitial reaction of extremely variable intensity. Small secondary cysts, called brood capsules, bud internally from the germinative layer and, by polyembryony, produce multiple protoscolices. A protoscolex is a scolex with the rostellum and suckers deeply withdrawn into the postsucker region. In humans, the slowly growing hydatid cysts may attain a volume of many liters and contain many thousands of protoscolices.

**TRANSMISSION, EPIDEMIOLOGY, AND GEOGRAPHIC DISTRIBUTION**

Dogs and other definitive hosts become infected upon ingesting organs of other animals that contain hydatid cysts or protoscolices released from recently ruptured cysts. *Echinococcus granulosus* has remarkable biologic potential; there may be as many as 40,000 tapeworms in a heavily infected dog, and each tapeworm sheds approximately 1000 eggs every 2 weeks. Dogs infected with *Echinococcus* tapeworms pass eggs in their feces, and humans become infected through fecal–oral contact, particularly in the course of playful and intimate contact between children and dogs. Eggs adhere to hairs around the infected dog's anus and are also found on the muzzle and paws. Indirect means of contact via soil, water, and contaminated vegetables, or through the intermediary of flies and other arthropods, may also result in human infections. Eggs of *E. granulosus* are capable of surviving snow and freezing conditions, remaining viable for at least 1 year on pasture, but they are susceptible to desiccation and will become incapable of hatching after only a few hours when exposed to direct sunlight. People of both sexes and all ages appear susceptible and opportunities for exposure are mainly related to direct

**FIGURE 114-3** Hydatid cyst of *Echinococcus granulosus* in liver of sheep showing protoscolices (P) in brood capsules, germinative layer (GL), and laminated membrane (LM). (H&E; bar = 100  $\mu$ m)

### *Echinococcus granulosus*

- Sheep and other pastoral strains

and indirect contact with infected dogs. Socioeconomic and cultural characteristics are among the best defined risk factors for human infection: uncontrolled dogs living closely with people, uncontrolled slaughter of livestock, and insanitary living conditions.<sup>9</sup> Whether it be among Arabs in Tunisia, Quechua Indians in Peru, Turkana tribesmen in Kenya, or Tibetans in China, these common factors are readily discernible. When dogs at risk of infection are maintained close to the family home, all members of the family may be exposed, or, as in certain cultural situations, one sex or the other may take responsibility for feeding and handling the dogs, thus favoring exposure of people of that sex.<sup>10,11</sup> Cystic echinococcosis imposes serious medical and economic disabilities on affected communities through the economic burden associated with infection in livestock as well as the disability and treatment costs associated with infection in humans.<sup>12,13</sup>

The greatest prevalence of CE in humans and nonhuman animals is found in countries of the temperate zones, including southern South America, the entire Mediterranean littoral, the southern and central areas of the former Soviet Union, Central Asia, China, Australia, and areas of Africa (reviewed in Schantz and others<sup>9</sup>). Consistently, highest prevalence is found among populations involved with sheep raising, thus emphasizing the overwhelming public health importance of the sheep genotype *E. granulosus* (G1). In certain regions of the former Soviet Union (e.g., Kazakhstan and Kyrgyzstan), changing agricultural practices and disruptions in regulatory policies have led to increased transmission in both lower animal and human hosts.<sup>13,14</sup> The cervid genotypes (G7 and G8) also commonly infect humans in northern North America and Eurasia; as

with the sheep genotype cestode, it is the synanthropic link through the dog that results in most human exposure.

In many countries of these regions, national diagnostic incidence rates have been reported to range from 5 to 20 per 100,000 population.<sup>9</sup> "National" rates are misleading, however, because most urban populations are at low risk; in rural endemic areas diagnostic incidence is manyfold higher. Furthermore, surveys of local populations using ultrasound imaging diagnostic techniques often measure CE prevalences of 2% to 6%.<sup>12,13</sup> In the United States, most infections are diagnosed in immigrants from countries in which hydatid disease is highly endemic; historically, this was mainly Italians and Greeks, but in recent years increasing numbers of cases have been diagnosed in people of Middle Eastern and Asian origin.<sup>9</sup> Sporadic autochthonous transmission is currently recognized in Alaska, Arizona, and New Mexico.

### DISEASE

There are numerous descriptions of the diverse clinical manifestations of CE (hydatid disease) in the medical and surgical literature.<sup>15–17</sup> Many human infections remain asymptomatic; hydatid cysts are frequently observed as incidental findings at autopsy or detected by abdominal ultrasound screening at rates much higher than the reported local morbidity rates. The severity and nature of the signs and symptoms produced by larval cestodes are extremely variable and never pathognomonic. The particular manifestations are determined by the site of localization of the cysts, their size, and their condition.

The incubation period of human hydatid infections is highly variable and often prolonged for several years. Cysts localized in the liver or lung may grow for many years before obtaining enough mass to cause symptoms; in contrast, those located in the brain or eye need reach only very small size before clinical symptoms appear. Age-specific prevalence of liver and pulmonary hydatid cysts increases gradually with age, suggesting that new infections continue to be acquired throughout the human life span. Most primary infections in humans consist of a single cyst; however, 20% to 40% of patients have multiple cysts or multiple organ involvement. The liver is the most common site of cyst localization (65%), followed by the lungs (25%); hydatid cysts are less frequently seen in the spleen, kidneys, heart, bone, and central nervous system. Cysts of the cervid (G7), or northern sylvatic, form localize predominantly in the lungs; however, the disease caused by this variant has been described as usually more benign and uncomplicated than that caused by the sheep strain.<sup>7</sup> In secondary echinococcosis, new cysts develop from released protoscolices after spontaneous or trauma-induced cyst rupture or during invasive treatment procedures.

The slowly growing hydatid cyst is well tolerated by the human host until it becomes large enough to cause dysfunction. Cyst rupture, often resulting from trauma, may cause a variety of immediate or delayed sequelae. Mild to severe anaphylactoid reactions (and, occasionally, death) may follow the sudden massive release of cyst fluid. In the lungs, ruptured cyst membranes may be evacuated entirely through the bronchi or retained to serve as a nidus for bacterial infection. Dissemination of protoscolices incidental to surgical treatment may result in multiple secondary disease. In one study of 106 patients, the rate of postoperative recurrence within 3 years was 11%<sup>15</sup>; however, postsurgical chemotherapy reduces this risk (discussed later).

Hydatid cysts of the liver may become relatively large before producing symptoms because of the large size and the distensible nature of the organ. Signs and symptoms may include hepatic enlargement with or without a palpable mass in the right upper quadrant, right epigastric pain, nausea, and vomiting. Rupture or leakage usually results in acute or intermittent allergic manifestations. Urgent complications existing at the time of initial presentation in 7% of Australian patients with hepatic cysts include traumatic or spontaneous rupture, thoracobilia, and biliary fistula.<sup>16</sup>

Intact hydatid cysts in the lungs may cause no symptoms, but leakage or rupture causes chest pain, coughing, dyspnea, and hemoptysis. Hydatid membranes may be coughed up, sometimes resulting in spontaneous cure. Emergency complications existing at the time of initial presentation include cyst rupture and secondary bacterial infection. Twenty percent to 40% of patients with pulmonary hydatidosis can be shown to have liver involvement as well.<sup>15-17</sup>

In most surgical series, 5% to 10% of the cases involve organs other than the lungs or liver.<sup>17,18</sup> The clinical manifestations of cysts in unusual localizations often present special difficulties and delays in diagnosis. The first symptom of cerebral cysts may be raised intracranial pressure or focal epilepsy, whereas kidney cysts may be manifested by loin pain or hematuria. Bone cysts are often asymptomatic until pathologic fractures occur, and because of the resemblance, they are often misdiagnosed as tuberculous lesions. Cysts in the heart

are especially dangerous because they may rupture and cause systemic dissemination of the protoscolices, anaphylaxis, or cardiac tamponade.

Although mortality rates associated with hydatid disease may appear low in comparison to those for some other infectious diseases, the morbidity associated with each case is considerable. Patients with hydatid disease often require multiple surgical interventions. Extensive secondary hydatid disease often becomes inoperable. Economic losses to affected families include surgical and hospital expenses as well as loss of income.<sup>12</sup> In Uruguay, it was shown that 60% of surgical patients were unable to return to normal activities for 4 months after leaving the hospital, and 40% were incapacitated for 6 months or longer.<sup>19</sup>

## PATHOGENESIS AND IMMUNITY

Intermediate hosts mount an early immune response to infection with *Echinococcus* larvae as evidenced by the specific antibody and cellular responses and protective immunity generated by a primary infection.<sup>20</sup> The immune response may be separated into two phases: The first is that directed against the hatched oncospheres attempting to penetrate the gut mucosa and establish themselves in the host tissues. The second phase is aimed at the established metacestode at the site of election. Immune effector mechanisms of the first phase are more successful in destroying the parasites than those of the second because established metacestodes have evolved highly effective mechanisms for evading the host's defenses. Evidence suggests that early oncospheres are highly vulnerable to attack by host defenses, but only briefly, and a race between parasite development and the host response occurs in the critical first few days of infection.<sup>21</sup> The explanation for the ability of larvae to persist indefinitely in the tissues of immunologically competent hosts has been of great interest to parasitologists; but understanding is incomplete.<sup>20,21</sup>

Antibody-mediated, complement-dependent destruction of oncospheres in the gut or at the tissue site of development is the most effective mechanism of host defense. Specifically activated B lymphocytes, eosinophils, neutrophils, and macrophages migrate to and concentrate in the vicinity of the developing larvae; however, the exact roles of cellular mechanisms in the immune response are not known. Once established in the tissues, the metacestode appears well protected from the host immune response. Although direct exposure to complement and immune serum readily causes lysis of protoscolices and other metacestode tissues, in vivo they somehow evade or counteract these effects. For *E. granulosus* cysts, this protective state appears related to sequestration of the parasite by the laminated and germinative membranes and host capsule, which greatly limit the exchange of high-molecular-weight substances between host and parasite. The host's capacity for developing a parasite-specific cellular response able to eliminate the parasite may be modulated by parasite-derived effector substances. Anticomplementary factors released by the metacestode may contribute to the evasion by causing complement depletion at the host-parasite interface. Larval cestodes may also induce a disturbance of normal immune function. Mice chronically infected with *E. granulosus* exhibit an alteration of the T cell populations resulting in suppression of normal immune responsiveness; these include

a polyclonal B cell activation, a marked decrease in mean T cell percentage but increase in suppressor cell activity, direct splenic T lymphocyte cytotoxicity to the metacestode, and impairment of the host defense potential by the formation of antihuman leukocyte antigen-reactive host antibodies. Other hypotheses proposed to account for prolonged survival of metacestodes include membrane fixation of blocking antibodies, which could interfere sterically with the attachment of protective antibodies or specifically sensitized cells. Several mechanisms may contribute to the parasite's defense simultaneously or at a different stage of the infection.<sup>21</sup>

Progress in developing effective vaccination against infection with oncospheres and immunotherapy of the metacestode have been reviewed by Lightowlers and colleagues.<sup>22</sup> The protoscolex appears to contain antigens that may be useful in immunotherapy, whereas the oncosphere contains antigens useful for vaccination against tissue-invading oncospheres. Antigens cloned from messenger RNA isolated from *E. granulosus*-hatched and -activated oncospheres successfully immunized lambs against challenge with infective eggs; vaccines based on these antigens may ultimately provide an additional tool for control and prevention of this infection. Possible immunotherapeutic molecules may be those involved with anticomplementary activity, those inducing changes in the host effector cell attack on metacestodes, and possible hidden antigens of the metacestode, such as serine proteases, cysteine proteases, or aspartyl proteases; however, immunotherapy is still experimental.

## DIAGNOSIS

The presence of a cyst-like mass in a person with a history of exposure to sheepdogs in areas in which *E. granulosus* is endemic supports the diagnosis of CE; noninvasive confirmation of diagnosis can usually be obtained by ultrasound or radiologic imaging and immunologic techniques.<sup>17</sup> Cystic echinococcosis must be differentiated from nonparasitic cysts, cavitary tuberculosis, mycoses, abscesses, and benign or malignant neoplasms.

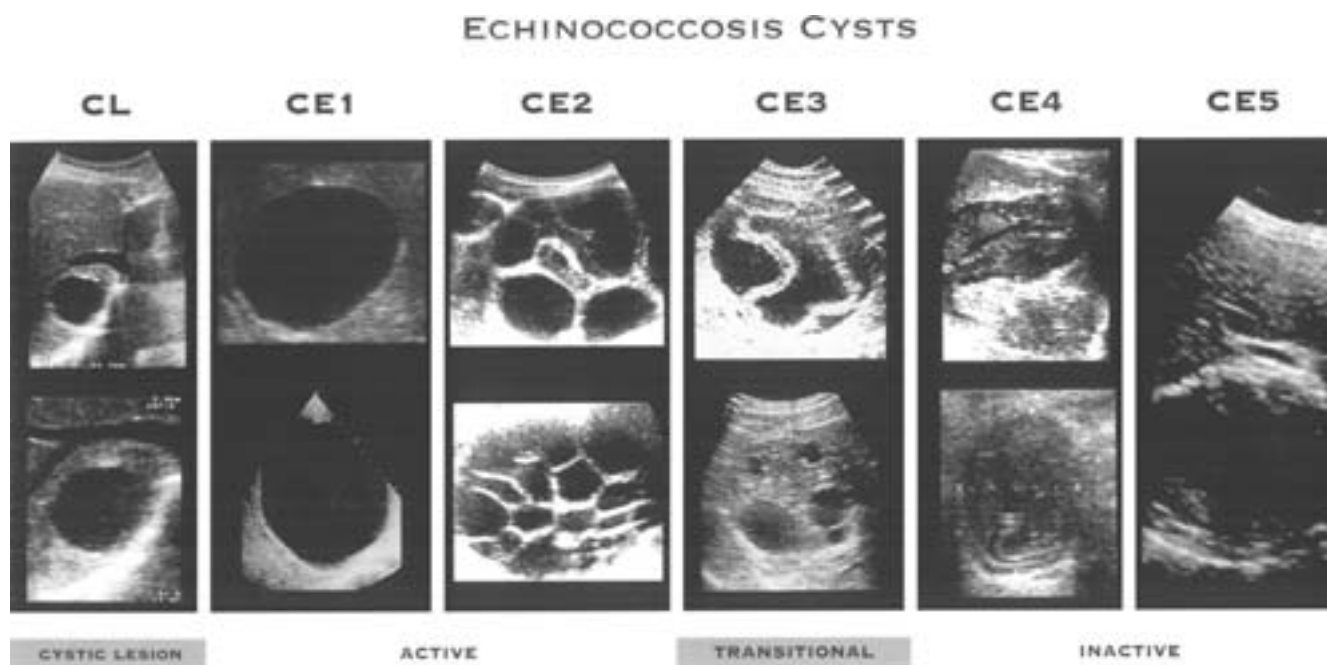

Radiography permits the detection of hydatid cysts in the lungs; however, in other organ sites, calcification is necessary for visualization. Computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound imaging are all useful for detecting and defining the extent and condition of avascular fluid-filled cyst(s) in most organs<sup>23,24</sup> (Fig. 114-4). These noninvasive imaging techniques have proved valuable for diagnosis and preoperative evaluation by staging the condition of the lesion (intact, unilocular, ruptured, complicated with daughter cysts, or calcified), the extent of the lesion in reference to other organs and vital structures, and identifying the presence of additional, occult lesions. Because of its relatively low cost and portability, ultrasonography has been used widely for screening, clinical diagnosis, and monitoring of treatment of liver and intra-abdominal cysts.<sup>24</sup> WHO/IWGE proposed a standard ultrasound classification of echinococcal cysts based on their ultrasound appearance consistent with the natural history of the disease and response to treatment that is useful for defining the extent and condition of the cyst(s)<sup>25</sup> (Fig. 114-5). The standardized classification scheme is intended to promote uniform standards of diagnosis and treatment and may be

applied to clinical management of patients as well as to field diagnostic surveys.

Serologic tests are useful for confirming presumptive imaging diagnoses; however, the limitations of serodiagnosis in CE must be understood to correctly interpret the findings. False-positive reactions, which, with tests using whole hydatid cyst fluid antigens, occur relatively frequently in people with other helminthic infections, cancer, and chronic immune disorders, may be misleading. Detectable specific immune responses have been associated with the location, integrity, and vitality of the larval cyst. Hepatic cysts are more likely to elicit an immune response than pulmonary cysts; nearly 50% of patients with single intact hyaline cysts of the lungs may be seronegative. Cysts in the brain and spleen are associated with lowered serodiagnostic reactivity, whereas those in bone appear to more regularly stimulate detectable antibody. Because fissuring or rupture of cysts is followed by an abrupt rise in titer of antibodies, it appears that the sensitivity of serologic tests is inversely related to the degree of sequestration of the hydatid antigens inside cysts, regardless of the location. Enzyme-linked immunosorbent assay (ELISA) and the indirect hemagglutination test are highly sensitive procedures for the initial screening of serum; diagnostic sensitivity varies from 60% to 90%, depending on the characteristics of the cases. Specific confirmation of reactivity can be obtained by demonstrating echinococcal antigens by immunodiffusion (arc 5) procedures or immunoblot assays (8-, 16-, and 21-kDa bands).<sup>26,27</sup> These latter serodiagnostic markers are the most *E. granulosus*-specific criteria described, but even they may be detected in serum of patients with other forms of echinococcosis and 5% to 10% of patients with *Taenia solium* cysticercosis. Circulating antigens are detectable in serum of many patients with CE. The sensitivity of antigen assays is relatively low in comparison with rates of antibody detection. However, since circulating antigens may be detectable in serum of some patients with negative or borderline antibody titers, antigen assays may be useful as a secondary test for

**FIGURE 114-5** World Health Organization/Informal Working Group on Echinococcosis (WHO/IWGE) classification of ultrasound images of cystic echinococcosis. There are six types of cysts: CL are cysts whose parasitic nature cannot be discerned, thus requiring further diagnostic tests to reveal their identity; CE1 and CE2 are active, usually fertile echinococcal cysts; CE3 are transitional in that their membrane integrity has been compromised either by the host reaction or by therapy and may reactivate to CE2 (active) or continue to regress to inactivity, types CE4 and CE5, which are solid cysts, with calcified rim in the latter. (From WHO/IWGE: International Classification of Ultrasound Images of Cystic Echinococcosis. Reproduced with the permission of WHO.)

clinical diagnosis.<sup>28</sup> Antigen assays are also useful for testing fluid from cysts of unknown origin.

In seronegative patients, a presumptive diagnosis may be confirmed by demonstrating specific antigens,<sup>28</sup> protoscolices, or hydatid membranes in the liquid obtained by percutaneous aspiration of the cyst. Closed aspiration may result in leakage of cyst contents with attendant risks of anaphylaxis or secondary hydatidosis; however, these risks can be minimized if the procedure is guided by ultrasound or CT and followed by benzimidazole treatment. Protoscolices released from cysts can sometimes be demonstrated in aspirates, sputum, or bronchial washings; identification of hooklets is facilitated by acid-fast stains. Eosinophilia is present in fewer than 25% of infected people. Although not widely available in clinical centers, polymerase chain reaction (PCR) techniques exist that are capable of differentiating genomic *E. granulosus* DNA from that of other species of *Echinococcus* and other infectious agents.<sup>29</sup>

## TREATMENT AND PROGNOSIS

Until recently, surgery was the only option for treatment of echinococcal cysts. However, chemotherapy with benzimidazole compounds and, more recently, cyst puncture, percutaneous aspiration, injection of chemicals, and reaspiration (PAIR) are increasingly used to supplement or even replace surgery as the preferred treatment.<sup>30</sup>

## Surgery

Surgical removal of intact hydatid cysts, when possible, has the potential to remove cysts and lead immediately to complete cure. The aim of surgery is total removal of the cyst while avoiding the adverse consequences of spilling its contents. Pericystectomy is the usual preferred procedure, but simple drainage, capitonnage, marsupialization, and resection of the involved organ may be used depending on the location and condition of the cyst(s).<sup>15–17,31,32</sup> The more radical the intervention, the higher the operative risk but the lower the likelihood of relapse, and vice versa. Surgery is the preferred treatment when liver cysts are complicated or located in certain organs—that is, the brain, lung, or kidney.<sup>31,32</sup> Surgery is contraindicated in patients who refuse, are pregnant, have pre-existing medical conditions that put them at risk, or in those with multiple cysts that are difficult to access. Surgical risks include those associated with any surgical intervention (e.g., anesthesia and infections) and those unique to echinococcosis (e.g., anaphylaxis and secondary recurrence). Operative mortality varies from 0.5% to 4.0% but increases with repeated interventions and in conditions of inadequate facilities.

Traditional surgical management of CE involves injection of protoscolicidal chemical solutions into the cyst(s), followed by evacuation, prior to further manipulations and extirpation of cysts. The use of formalin is no longer acceptable for intracystic injection because of the danger of resultant

sclerosing cholangitis.<sup>33</sup> Currently used compounds, including 70% to 90% ethyl alcohol and 15% to 20% hypertonic saline, have relatively low risk, but all have been reported to cause some complications. Few of these compounds are registered for parenteral or intraoperative use, and it is often difficult to accurately estimate the volume of cysts or determine if an intrabiliary communication exists. Given these considerations, and the current alternatives of peri- or postoperative chemotherapy<sup>34</sup> or both, perioperative injection of protoscolicidal chemicals should not be practiced as a routine procedure.

## Chemotherapy

Documentation of experience with chemotherapy with benzimidazole compounds is extensive, and the medical approach can be recommended for many patients. Approximately one-third of patients treated with benzimidazole drugs have been cured of their disease (e.g., collapse or solidification of cysts), and higher proportions (30% to 50%) have responded with significant regression of cyst size and alleviation of symptoms.<sup>35–39</sup> However, between 20% and 40% of cases do not respond favorably. In general, small (<7 mm diameter) isolated cysts, surrounded by minimal adventitial reaction, respond best, whereas complicated cysts with multiple compartments or daughter cysts, or with thick or calcified surrounding adventitial reactions, are relatively refractory to treatment. Both albendazole 10 to 15 mg/kg body weight per day and mebendazole, 40 to 50 mg/kg body weight per day for 3 to 6 months have demonstrated efficacy. Some investigators who have compared both drugs concluded that albendazole has slightly greater efficacy in terms of rates of complete cure and improvement; the more consistent response obtained with albendazole may be related to its superior pharmacokinetic profile that favors intestinal absorption and penetration into the cyst(s).<sup>36,39</sup> Adverse reactions (neutropenia, liver toxicity, alopecia, and others), reversible on cessation of treatment, have been noted in a minority of patients treated with both drugs. The reported variability in response to medical treatment suggests that the details of treatment, such as dosage, duration, and length of follow-up, must be determined individually for each case; it seems that a minimum duration of treatment is 3 months. The long-term prognosis in individual patients is difficult to predict; therefore, prolonged follow-up with ultrasound or other imaging procedures is needed to determine the eventual outcome.<sup>37,38</sup>

Another important use of chemotherapy is as adjunct to surgery. Albendazole has been administered to patients prior to surgery for the intended purpose of facilitating the safe surgical manipulation of the cyst(s) by inactivating protoscolices, altering the integrity of cyst membranes, and reducing the turgidity of the cysts. Experimental studies support this rationale.<sup>17</sup> Benzimidazole therapy is recommended for prevention of recurrent disease secondary to the spillage of contents of cysts after spontaneous or accidental rupture. Following such accidents, preventive treatment recommendations are 1 to 3 months continuously of mebendazole or albendazole.<sup>37</sup> Praziquantel 40 mg/kg body weight also has high protoscolicidal activity and may be useful for postspillage preventive therapy<sup>34</sup> or as a protoscolicidal agent in the PAIR procedure<sup>38</sup> (discussed later). Although praziquantel has shown

significant destructive activity on cyst germinal membranes *in vitro* and *in vivo*, sometimes greater than that of benzimidazoles, the drug has not been consistently efficacious against established hydatid cysts.<sup>37</sup> Combining praziquantel with albendazole was superior to albendazole alone as preoperative therapy.<sup>40</sup>

Contraindications to chemotherapy include patients with chronic hepatic disease and bone marrow depression. Since benzimidazole drugs are teratogenic, they should never be administered to pregnant women. Treatment of pregnant women, unless their disease is life-threatening, probably should be aimed at reducing discomfort until term, after which they can be treated with one of the previously discussed approaches.

## PAIR

Another option for the treatment of hydatid cysts in the liver and some other locations is percutaneous puncture using sonographic guidance, aspiration of substantial amounts of the liquid contents, and injection of a protoscolicidal agent (e.g., 95% ethanol or 15% to 20% hypertonic saline) for at least 15 minutes, followed by reaspiration (PAIR).<sup>41,42</sup> Reported experiences with this approach suggest good results in terms of efficacy and safety.<sup>43–51</sup> Clinical consultants of the WHO/IWGE have prepared a practical guide to the PAIR procedure.<sup>48</sup>

PAIR is indicated for patients with single or multiple cysts in the liver, abdominal cavity, spleen, and kidney. Echinococcal cysts with ultrasound appearances of “liquid cysts” (ultrasound image types CE1 and CE3 with detached endocyst)<sup>25</sup> (see Fig. 114-5) respond favorably to the procedure.<sup>48</sup> PAIR is contraindicated for inaccessible or superficially located liver cysts, in those with multiple daughter cysts (“honeycomb” appearance on imaging), for inactive or calcified cystic lesions, and for cysts with biliary communication. To avoid sclerosing cholangitis, this procedure must not be performed in patients whose cysts have biliary communication; the presence of the latter can be determined by testing the cyst fluid for the presence of bilirubin by endoscopic retrograde cholangiopancreatography (ERCP) or, preferably, by injection of contrast medium following aspiration and prior to injection of the protoscolicidal agent. Complications have included secondary infection of the cavity, acute allergic reactions, and recurrence<sup>47</sup>; however, these have been managed successfully. Applications of PAIR to pulmonary cysts, employed as an alternative in patients who have failed medical therapy, have been associated with frequent complications.<sup>49</sup>

The physician must be prepared to treat an allergic reaction should it occur. The possibility of secondary hydatidosis resulting from accidental spillage during this procedure can be minimized by concurrent treatment with benzimidazoles; indeed, a report suggests that combined treatment (PAIR with albendazole) may improve the results in comparison with either chemotherapy or PAIR alone.<sup>50</sup> The recommended treatment course is 4 days prior to and 1 month (albendazole) or 3 months (mebendazole) after the PAIR procedure. For treatment of uncomplicated cysts in the liver, Khuroo and coworkers<sup>51</sup> reported that, in comparison with patients who underwent surgical intervention (cystectomy), patients treated by PAIR followed by 8 weeks of albendazole chemotherapy had comparable rates of cyst disappearance (88% vs. 72%) but had reduced hospital stay (4 vs. 13 days) and reduced risk of complications (32% vs. 84%).

Conventional PAIR, using fine needles, is less effective in treating multivesicular cysts (WHO CE2 and “solid” CE3; see Fig. 114-5) than univesicular cysts (CE1 and CE3 with detached endocyst); recurrent cyst growth is common following treatment of these former types of cysts with PAIR.<sup>47</sup> Alternative percutaneous approaches to treatment have been proposed for these types of cysts, including trocar aspiration/drainage of the cyst matrix using large bore catheters or trocar devices<sup>52,53</sup> or inactivation of the germinal layer using a thermal treatment similar to that used for treatment of neoplasms.<sup>54</sup> Data on the long-term outcome of percutaneous treatment of these complex-type hydatid cysts are limited, and long-term follow-up is needed to evaluate effectiveness.

The PAIR procedure should only be performed by experienced physicians with adequate surgical backup support to deal with complications. The procedure is minimally invasive and less expensive than surgery.<sup>55</sup> Reported experiences with this approach suggest good results in terms of the absence of acute complications and recurrence. A meta-analysis concluded that in comparison to conventional surgical treatment, PAIR plus chemotherapy was associated with greater clinical and parasitologic efficacy, fewer recurrences, lower morbidity and mortality, as well as shorter hospital stays.<sup>56</sup> The development and use of ultrasound imaging technology for clinical diagnosis and population screening has provided significant improvements for abdominal forms of echinococcosis and has provided new information on the natural history of the disease. It is now clear that many, if not the majority of cases of CE have a benign prognosis. This knowledge has led to new, unanswered questions about the necessity for, criteria for, and selection of appropriate treatments. Further long-term observations and multicenter comparative trials of various interventions and placebo are required to answer these questions.

### Monitoring Results of Treatment

It has been observed that in echinococcosis, it is easier to prove treatment failure than treatment success<sup>17</sup>; however, noninvasive methods for monitoring cyst size, consistency, and integrity have substantially improved our ability to assess viability of hydatid cysts. The occult nature of the hydatid cyst confounds post-treatment evaluation. Objective response to treatment, whether surgery or chemotherapy or both, is best assessed by repeated evaluation of cyst(s) size and consistency at 3-month intervals with ultrasound imaging or at longer intervals with CT or MRI. Since the time of appearance of recurrence is extremely variable, monitoring should be continued for 3 or more years. Changes in titers of serologic tests have not by themselves been able to define the outcome of chemotherapy<sup>36</sup> or PAIR, presumably because of continued antigenic stimulation from parasitic tissue. In contrast, following successful radical surgery, antibody titers decline and sometimes disappear; titers rise again if secondary hydatid cysts develop.<sup>18,57</sup>

### PREVENTION AND CONTROL

*Echinococcus granulosus* has been viewed as highly vulnerable to the implementation of preventive measures, at least in theory. When only synanthropic hosts under human control are involved, the cestode cycle can be interrupted if dogs are prevented from consuming infected viscera from sheep

and other domestic ungulates. Indeed, there are a number of successful examples of echinococcosis control, achieved on a national or regional scale, that confirm that *E. granulosus* is relatively unstable in synanthropic hosts and responds readily to comprehensive and consistently applied measures of intervention.<sup>9</sup>

The earliest successful program was that in Iceland initiated nearly 130 years ago when cystic hydatid disease was recognized as affecting approximately one of every six Icelanders.<sup>9</sup> A uniquely effective health education campaign sensitized the entire population to the disease, and subsequent measures virtually eliminated home slaughter of sheep; the result was gradual elimination of transmission. By the 1950s, echinococcosis was considered eradicated from Iceland. Programs initiated in New Zealand (1959) and Tasmania (1965) were primarily based on education of rural populations and motivating them to change their practices. Strict control and prohibition of farm slaughter were key features in these programs. The initially voluntary nature of the programs was reinforced by legislative acts and strengthened efforts at enforcement as the programs progressed. This policy proved highly successful: The number of infected dogs declined steadily throughout the campaigns. The decline in canine infection preceded decreases in the prevalence of infection in sheep and young cattle and a reduced number of cases in humans diagnosed annually. In New Zealand, the first year when no dogs were found infected was 1985–1986, and hydatid cysts in sheep are now rare. No new human cases of hydatid disease have been reported in children or adults younger than 19 years old since 1977. CE has been declared provisionally eradicated in both Tasmania and New Zealand. A program in Cyprus benefited from very aggressive stray dog elimination and strict control of working dogs and those kept as pets. All used diagnostic purging of dogs with arecholine as a surveillance technique for monitoring the effectiveness of the program and identifying problem farms. Tasmania quarantined infected dogs and infected sheep flocks. Regional programs in Argentina (1970) and Chile (1978) benefited from the advent of the highly effective echinococcicidal drug praziquantel. Monitoring of surveillance data in all these programs documented the reduction of prevalence in dogs, animal intermediate hosts, and humans.<sup>9</sup>

The epidemiologic characteristics associated with the transmission of echinococcosis in the endemic regions where control interventions have been successful were varied, as were the events leading to official commitments to undertake control efforts and the specific technical measures employed. Nevertheless, sustained implementation of control measures resulted in a successful interruption of transmission, and it seems that the fundamental requirements for effective control are now tried and proven in a variety of epidemiologic situations.<sup>58</sup> Control measures with proven usefulness include health education, stray dog control, registration of owned dogs, routine diagnostic testing and treatment of dogs, restrictions or controls on commercial and home slaughter of sheep and other livestock, and enactment and enforcement of legislation supporting the other measures. Since the available technology has improved throughout the years, the degree and the rapidity of demonstrable progress have, in part, reflected the degree of sophistication of the technology. Future progress in technology (e.g., the development of a vaccine for sheep<sup>22</sup>) will

further improve the technical possibilities for effective control. The immediate prospects for further progress in control of hydatid disease depend on the development of adequate surveillance systems and careful documentation of the disease in all important hosts in order to characterize the quantitative dynamics of transmission and the costs and benefits of different control strategies.<sup>58,59</sup>

It must be noted that the positive achievements of successful control programs, however significant at the local level, have not markedly changed the global distribution and public health importance of hydatid disease. In most endemic areas, effective control has not been achieved or even attempted. Much remains to be done.

## ■ Alveolar Echinococcosis (*Echinococcus multilocularis*)

### AGENT

The causative agent of AE was first recognized by Virchow in 1855 as being the larval stage of an *Echinococcus* cestode, but the relationship of this organism to the adult form in canids and its taxonomic designation remained unresolved for more than 100 years. Rausch and Schiller<sup>59</sup> described the life cycle and morphologic characteristics of an Alaskan cestode that was distinct from *E. granulosus*, and they named this organism *Echinococcus sibiricensis*. In Germany, Vogel<sup>60</sup> demonstrated that this cestode was identical to the causative agent of alveolar hydatid disease in Eurasia and confirmed Leuckart's earlier designation of *E. multilocularis* as having priority.

Although there is suggestive evidence of variation in morphology, pathogenicity, developmental characteristics, and host specificity between populations of *E. multilocularis* from Europe, Alaska, and central North America, few comparative data are available and the existence of distinct strains remains unconfirmed.<sup>1</sup> Rausch and Richards<sup>61</sup> did extensive morphologic studies and experimental infection trials and concluded that, except for indications of differences in the ability of the larvae to develop in rodents of various species, the cestode in central North America appears to be indistinguishable from that of the northern tundra zone. In comparison to the genetic variability in *E. granulosus*, direct genomic variation in different geographic populations of *E. multilocularis* is minor.<sup>2,62</sup>

Postoncospherical development of larval *E. multilocularis* in susceptible rodent hosts is fundamentally the same as that of *E. granulosus*, except that the primary vesicle gives rise to others by continuous exogenous budding, to produce a larval mass composed of hundreds of contiguous vesicles that may occupy more than one-half of the invaded hepatic lobe (Fig. 114-6).

There is no limiting membrane of host or parasite origin. Growth of the larva from the single primary vesicle to the compound multivesicular stage with infective protoscolices may be completed in as short a period as 2 months or as long a time as 7 months, depending on conditions for growth in the host. The rapid rate of development of *E. multilocularis* compared with that of *E. granulosus* is an adaptation to the short-lived rodent intermediate hosts. The number of protoscolices within a larval mass derived from a single embryo is

**FIGURE 114-6** *Echinococcus multilocularis* in liver of infected rodent showing characteristic alveolar-like microvesicles with protoscolices. (H&E; bar = 100  $\mu$ m)

highly variable within and between species of hosts but may number several thousand.

### TRANSMISSION, EPIDEMIOLOGY, AND GEOGRAPHIC DISTRIBUTION

The life cycle of *E. multilocularis* involves foxes, coyotes, and arvicolid rodents; *Ochotona* sp., a small lagomorph, is an important intermediate host in Central Asia (Fig. 114-7). Domestic dogs and cats also become infected; cats are less efficient definitive hosts, however, and develop fewer, less fecund adult worms in comparison with dogs.<sup>63</sup>

Infection rates in the natural hosts, both intermediate and definitive, are influenced by the numerical densities of these mammals as well as the kind of predator-prey relationship that exists between them. In the northern tundra zone, a strongly defined predator-prey relationship exists between arctic foxes and microtine rodents. The arctic fox feeds almost exclusively on microtine rodents. In studies carried out during different years, infection rates in foxes and voles ranged from 40% to 100% and from 2% to 16%, respectively.<sup>59,64</sup> The variations correlated closely with fluctuations in the host populations; the parasites were least numerous when the populations of hosts were reduced, but infection rates were additionally influenced by habitat and climatic season. The number of worms in infected arctic foxes usually exceeds 100,000 to 200,000 per animal, but they apparently cause no adverse effects. Most worms are eliminated spontaneously 3 or 4 months after infection, although some may remain for 7 months or longer; however, these are senescent and can no longer produce eggs.<sup>61</sup>

Being largely confined to life cycles involving foxes and arvicolid rodents, in ecosystems generally separate from humans, exposure of humans to *E. multilocularis* is relatively less common than exposure of humans to *E. granulosus*, the cause of cystic echinococcosis.<sup>9</sup> Fox trappers and other people who work with foxes or their fur would appear to be relatively frequently exposed to eggs of *E. multilocularis*, but these occupations have not been associated with higher rates of infection.<sup>65-67</sup> In most endemic areas, there are few well-defined

**FIGURE 114-7** Life cycle and principal and alternative hosts for *Echinococcus multilocularis*.

individual risk factors for infections; however, infection rates are highest in people resident in rural areas where the cestode is endemic. There is ecological overlap to humans because domestic dogs or cats may become infected when they eat infected wild rodents, and infected pets are an important source of infection for humans.<sup>66-68</sup> It remains unclear whether genetic factors in humans play a role. Associations between MHC polymorphism and clinical presentation have been demonstrated.<sup>69,70</sup>

Hyperendemic foci have been described in some Native American villages of the North American tundra<sup>61,68</sup> (now

largely disappeared) and in China,<sup>10,11,71</sup> where local dogs regularly feed on infected commensal rodent and lagomorph intermediate hosts. In these circumstances, indirect or direct contamination from feces of infected dogs appears to be the most important source of infection, and human infection prevalence may reach 2% to 6%.<sup>10,11</sup>

*Echinococcus multilocularis* has an extensive geographic range in the Northern Hemisphere, widespread and increasing in Europe, most of northern Eurasia, from Bulgaria and Turkey through most of Russia, and the newly independent nations of the former Soviet Union, extending eastward to several of

*Echinococcus multilocularis*

Circa 1990

Circa 2000

### *Echinococcus multilocularis* in Central Europe

the Japanese islands.<sup>9</sup> In North America, the cestode is found throughout the northern tundra zone and in a discontinuous zone to the south. In the Middle East, *E. multilocularis* is reported in eastern Turkey and Iran. One human case has been reported in northern India.<sup>72</sup> The report of human cases from a mountainous region of northern Tunisia was the first indication of the occurrence of *E. multilocularis* in North Africa.<sup>73</sup>

Recent surveys in Central Europe have extended the known distribution of *E. multilocularis* from four countries at the end of the 1980s to at least 11 countries in 1999. The incidence of diagnosed disease in humans remains low, between 0.02 and 1.4 per 100,000 for entire countries or larger regions of endemicity.<sup>74</sup> Between 1982 and 2000, 559 cases of alveolar echinococcosis in humans were reported voluntarily from nine European countries to the European Echinococcosis Registry.<sup>75</sup> The cestode appears to have spread eastward in Europe in association with increased populations of foxes, and this may herald the emergence of AE in humans in central Eastern Europe. Surveys of foxes in Germany and France carried out in the mid-1990s compared recent data with that collected in the 1970s and 1980s and documented higher fox densities as well as increased prevalences of *E. multilocularis* infection.<sup>76,77</sup> New human cases have been reported during the past 10 years in several European countries previously considered nonendemic: Belgium, The Netherlands, Luxembourg, Czech Republic, Slovak Republic, Poland, Italy, Slovenia, Hungary, Bulgaria, and Romania.<sup>74</sup> Increasing fox populations, increasing encroachment of foxes into urban areas, and spillover of *E. multilocularis* infection from wild carnivores to domestic dogs and cats might presage increased public health risks of AE.<sup>78,79</sup>

The known distribution and prevalence of infection in foxes and coyotes have increased in central North America. Before 1964, there were no reports of *E. multilocularis* in North America south of the Arctic tundra zone, but in that year it was reported in foxes and rodents in North Dakota.<sup>80</sup> By 1969, parasitologic surveys revealed that the cestode was established in cycles involving red foxes, coyotes, and deer mice in North and South Dakota, Minnesota, Montana, and Iowa and the Canadian provinces of Manitoba, Saskatchewan, and Alberta.<sup>61,81</sup> The known range was further extended in the 1970s and 1980s by reports from Wyoming, Nebraska, Wisconsin, Illinois, Indiana, Michigan, and Ohio.<sup>82–85</sup> Exposure of humans appears to be rare. To date, only two people are known to have acquired their infections in the endemic region

in central North America: a 54-year-old man from Manitoba, Canada, and a 60-year-old woman from Minnesota<sup>67</sup>; however, the potential exists for a more serious public health problem.<sup>9,65</sup>

### DISEASE

After ingestion, cestode eggs hatch and release embryos (oncospheres) in the small intestine. Penetration through the mucosa leads to blood-borne distribution to the liver and other sites, where larval development begins. The primary infection in humans is in the liver, but direct extension to contiguous organs, as well as hematogenous metastases to the lungs and brain, is not uncommon. Alveolar echinococcosis in humans is comparable to that in the natural intermediate hosts (viz., the primary larval lesion develops in the liver) but differs in that the larval mass is inhibited by the host from completing its development and remains in the proliferative stage indefinitely. The larval mass resembles a malignancy in appearance and behavior; thus, it continues to invade and destroy the hepatic parenchyma and surrounding tissues, and retrogressive stages within the mass result in necrosis of the central portion (Fig. 114-8). In chronic AE infections, the

**FIGURE 114-8** Alveolar echinococcosis lesion involving the left lobe of the liver following surgical resection. Note extensive destruction of the hepatic parenchyma and the necrosis producing a central abscess. (Courtesy of Dr. W. A. Gamble, Minneapolis.)

lesion consists of a central necrotic cavity filled with a white amorphous material that is covered with a thin peripheral layer of dense fibrous tissue.<sup>86</sup> There are focal areas of calcification and extensive infiltration by proliferating vesicles. Protoscolices are rarely observed in infections of humans. Host tissue is directly invaded by extension of the budding and proliferating cyst wall, causing a pressure necrosis of surrounding host tissue (Fig. 114-9). A fibrous tissue reaction usually surrounds the larval mass, and a moderate inflammatory reaction is restricted to active lesions. Symptoms are often vague, with presenting complaints of right upper quadrant discomfort or pain, weight loss, and malaise. Occasionally, symptoms related to pulmonary or cerebral metastases may constitute the presenting symptoms.<sup>87</sup>

Cases of AE are typically characterized by an initial asymptomatic incubation period of 5 to 15 years and a subsequent chronic course. Because of the natural history of the disease, the nonspecificity of early symptoms, and perhaps because health-care providers may not be familiar with the disease, diagnosis is often delayed until an advanced and inoperable stage. Alveolar echinococcosis is a serious disease; although some *E. multilocularis* infections in humans resolve spontaneously in the early stages of the disease,<sup>88</sup> the death rate in progressive, clinically manifest cases is high. With or without surgery, reported mortality rates have ranged between 50% and 75%.<sup>17</sup> Screening of populations at risk by abdominal imaging (ultrasound or CT scans) followed by specific immunodiagnostic techniques detects cases in the early stages of alveolar echinococcosis and, consequently, improves the prognosis by reducing complications, morbidity, and mortality.<sup>74</sup> A clinical classification system for human AE has been proposed and designated as the PNM system (P, primary lesion; N, involvement of neighboring organs, including lymph nodes; and M, metastases). The PNM classification follows closely the TNM classification of hepatocellular carcinoma and allows an anatomical description of the lesion at initial presentation as well as a prospective staging of the disease (stage I to stage IV).<sup>89</sup> The PNM system aids a precise description of the disease at diagnosis, providing a baseline for evaluation of treatment strategies.

**FIGURE 114-9** *Echinococcus multilocularis* larvae in liver tissue of infected patient. Irregular cuticular vesicles are prominently stained by the positive acid-Schiff reaction. (Bar = 100  $\mu$ m)

## PATHOGENESIS AND IMMUNITY

Immunologic or constitutional resistance to infection or immunologic resistance to disease following infection may be common features.<sup>90</sup> Although high levels of parasite-specific antibodies are characteristic of infections, antibodies do not appear to restrict the growth of the metacestode. In contrast, T lymphocyte interactions are of great immunopathologic significance. Periparasitic granulomas—mainly composed of macrophages, myofibroblasts, and T cells—contain a large number of CD4+ lymphocytes in patients with so-called abortive or died-out lesions, whereas in patients with active metacestodes, the number of CD8+ cells is increased.<sup>91</sup> An association between lymphoproliferative responsiveness and mechanisms of resistance or susceptibility to *E. multilocularis* infections has also been suggested by comparative in vitro lymphocyte stimulation assays in patients with different courses of disease. Interleukin-5 and interleukin-10 were shown to be the predominant cytokines produced by peripheral blood mononuclear cells in patients with AE, indicating the activation of Th2 immune responses in disease.<sup>92–94</sup> Whereas the innate immune system seems to be highly activated, there is no specific memory T cell response detectable in the chronic state of the disease.<sup>95,96</sup> It seems that viable larvae efficiently suppress specific cellular immune responses.

Clinical observations have allowed discrimination between two groups of people infected with *E. multilocularis*: those who develop disease, thus reflecting susceptibility to unlimited metacestode proliferation, and those in whom metacestode proliferation has ceased, who harbor intrahepatic died-out lesions, and thus reflect resistance to disease. A third group of people demonstrating putative immunologic resistance to infection has become evident in seroepidemiologic surveys. Many apparently exposed people (as evidenced by seroconversion to specific *E. multilocularis* antigen, i.e., Em2) do not permit postoncospherical parasite development and are assumed to be resistant.<sup>90</sup>

Murine models of AE have shown that a pre-existing larval infection can prevent or suppress the development of a secondary infection, but once a primary infection is established in susceptible laboratory rodents, the initial *E. multilocularis* metacestode appears well protected from the host immune response.<sup>97</sup> Depletion of T cells enhances metastasis formation in mice. Activated macrophages appear to be key participants in the immune response because they adhere to the metacestode; the cestode grows and metastasizes despite a marked lymphoproliferative activity in the B and T cell areas of lymphoid tissue. The parasite may survive by actively impairing cellular mechanisms of recognition and neutrophil chemotaxis in experimentally infected mice. Susceptibility and resistance to infection with *E. multilocularis* metacestodes may depend on genetically based immunologic factors, as evidenced by marked differences in susceptibility to infection in different mouse strains.

## DIAGNOSIS

Clinical onset of AE typically occurs in people of advanced age. In the large European Registry, mean age at first diagnosis was 52.5 years, with a range of 5 to 86 years and a gender ratio of 1:1.2.<sup>75</sup> The disease closely mimics hepatic

carcinoma and is a challenge to diagnose, even in endemic regions. The most frequent morphological profile of AE is an intrahepatic heterogeneous, infiltrative, and destructive mass, with irregular outlines, and an avascular and necrotic center that appears on abdominal ultrasound as a hypoechoic lesion with a hyperechoic rim. The usual CT image of the same lesion is a hypodense structure with a density of 0 to 25 Hounsfield units, often showing characteristic hyperdense, plaque-like calcifications.<sup>98</sup> The multivesicular pattern of the lesion is most clearly demarcated on T1-weighted MRI images, whereas the nonhomogeneous character of the lesion is appreciated on T2-weighted images (Fig. 114-10). Fluoro-desoxyglucose positron emission tomography (FDG-PET) was reported to be a reliable method for the determination of metabolic activity in and around *E. multilocularis* liver lesions, thereby allowing the “functional imaging” of infectious lesions.<sup>99,100</sup>

Most patients with AE respond to infection with synthesis of parasite-specific antibodies, including all isotypes of immunoglobulins.<sup>90</sup> Serologic tests are usually positive at high titers; highly specific antigens<sup>101–103</sup> have been identified and synthesized that, when used in serologic assays, are highly sensitive and specific for diagnosis of AE and can distinguish this infection from CE (*E. granulosus*) and other forms of echinococcosis.

As in CE, serologic tests are more useful for evaluating prognosis following surgery than for determining outcome of chemotherapy.<sup>104</sup> Antibodies persist indefinitely in the serum of patients treated by chemotherapy; however, negative seroconversion occurs within 1 year in patients whose lesion is completely extirpated by surgery. Antibodies of the IgG1 and IgG4 isotypes are the most sensitive IgG responses in AE, and monitoring of these isotypes tended to correlate with active vs. inactive disease and successful treatment.<sup>105</sup>

In seronegative patients, PCR reactions for detection of echinococcal-specific RNA or DNA in closed or open biopsy specimens have been developed and may confirm the diagnosis.<sup>106–108</sup> Exploratory laparotomy, sometimes performed to confirm the diagnosis and delineate the size and extent of

the invasive lesion, should be avoided because of potential spread of larval tissue into the peritoneal cavity.

## TREATMENT

Clinicians familiar with this disease emphasize that management of AE, characterized by a malignant-like proliferating cestode, is extremely difficult and usually requires radical surgery, ideally at an early stage, and long-term or lifelong chemotherapy with benzimidazoles.<sup>17,37,109</sup> Choosing from the variety of treatment options requires specific clinical experience; therefore, patients should be referred to recognized national or regional AE treatment centers.<sup>37</sup> Experience in AE screening programs in Japan and elsewhere has shown that early diagnosis reduces morbidity and mortality. Surgical treatment usually requires extensive resection of host tissue (i.e., partial or total resection of the affected hepatic lobe) and should only be performed if a safety margin of 2 cm can be achieved.<sup>110</sup> In cases that are inoperable, in which resection is incomplete or partial, or in cases in which there are metastases to the brain or lungs, surgery must be followed by benzimidazole chemotherapy. In clinical trials with patient follow-up of many years, mebendazole administered continuously for up to 10 years at doses of 40 to 50 mg/kg body weight per day inhibited progression of AE and reduced lesion size in approximately half of treated cases.<sup>111,112</sup> In patients administered albendazole for repeated periods of 28 days at doses of 10 mg/kg body weight per day with treatment-free intervals of 14 days or given continuously, the results were similar to those described with mebendazole.<sup>112–114</sup> Benzimidazole treatment enhanced length and quality of life. In most cases, chemotherapy with either drug was not parasitocidal; however, there are some indications that parasite death may occur after treatment for many years.<sup>37,111,114</sup> In Europe, postoperative chemotherapy for 2 years is routinely carried out after radical resection, with careful monitoring of the patient for a minimum of 10 years for possible recurrence.<sup>115</sup>

Liver transplantation is not recommended as a treatment option since larval infiltration of the transplant from the surrounding tissue is frequent. However, in patients with terminal liver disease, transplantation may prolong survival.<sup>116</sup>

## PREVENTION AND CONTROL

In regions where the infection is enzootic in sylvatic cycles, emphasis should be placed on personal preventive measures, including avoiding contact with foxes and other potentially infected definitive hosts and carefully washing and cooking vegetables and other fresh produce. Control of working and pet dogs and cats must be practiced to prevent them from preying on rodents and, thereby, becoming infected.<sup>9,66</sup> Infections in dogs and cats that are liable to eat infected rodents can be prevented by prophylactic treatments with praziquantel (5 mg/kg body weight); under conditions of intense transmission, prophylactic treatments would have to be given at intervals no longer than 30 days (the prepatent period of the cestode) to most effectively prevent excretion of eggs. People living in areas where *E. multilocularis* is enzootic should be educated about the potential dangers, to promote better personal hygiene and sanitation and to motivate them

**FIGURE 114-10** Images of alveolar echinococcosis, coronal views. *Left*, Computed tomographic (CT) image of liver of a patient with alveolar echinococcosis. *Middle*, The same lesion visualized by 18-fluor-desoxyglucose positron emission tomography (FDG-PET). Note enhancement of the periphery of the image indicating enhanced metabolic activity of host cells in response to the viable *E. multilocularis* larvae (arrow). *Right*, PET-CT; the coloration indicates different intensities of metabolic activity.

to take effective measures to prevent their pets from eating rodents.

Active intervention for control of *E. multilocularis* presents special difficulties because the primary cycle is almost always sylvatic. In most regions where *E. multilocularis* is enzootic, controlling the cestode by eliminating its sylvatic hosts would be impractical for economic and logistic reasons or unacceptable for ecological reasons.<sup>9</sup> Two approaches to control of infection in sylvatic hosts, one mainly of historical interest and the other experimental, are described next. Where exposure of humans is mainly related to cycles involving synanthropic hosts (i.e., dogs), protection might be achieved by regular taeniocidal treatments of dogs; one such demonstration project is described here.

### Control in Sylvatic Life Cycles

Approximately 25 years after its introduction in foxes translocated from the Kuril islands, *E. multilocularis* was eliminated from Rebun Island in Japan by eliminating the cestode's hosts. Between 1950 and 1955, 2026 foxes and 3224 dogs were captured and killed; without adequate numbers of definitive hosts *E. multilocularis* was soon eliminated. This is the only known instance in which *E. multilocularis* has been eradicated from an area where it was previously enzootic. However, *E. multilocularis* continues to spread on Hokkaido Island and threatens to become established on the mainland of Japan.<sup>117</sup>

Increases in the fox populations in areas of Europe have led to introduction of *E. multilocularis* into urban environments. Although this has not been associated with apparent increases in infections in humans, it has raised public health concerns. In Zurich, Switzerland, monthly distribution of praziquantel-containing baits during a 16-month period resulted in significantly decreased prevalence in foxes (from 39% to 67% to 1.8% to 5.5%), whereas infection in foxes remained the same in nonbaited control areas.<sup>118</sup>

### Control in Synanthropic Cycles

Where it is determined that dogs frequently become infected by preying on commensal rodents, thus contributing significantly to local environmental contamination with eggs and potential human exposure, periodic mass echinococcal treatments of dogs is one approach to reducing the risk of human infection. This was evaluated in a 10-year field trial in a village on St. Lawrence Island, Alaska, where *E. multilocularis* was hyperendemic.<sup>119</sup> All dogs in this village were given praziquantel 5 mg/kg body weight at monthly intervals. This was effective in reducing egg contamination as evidenced by an average 83% reduction in infection prevalence in voles during the course of the trial; prevalence in locally captured voles declined from an average of 29% at the beginning of the trial to less than 5% at the end. Fluctuations in the annual incidence of infection in voles appeared to be related to the degree that dog owners cooperated in making their pets available for treatment. This control method, which is relatively costly, may be applicable to other regions where synanthropic cycles create a high risk for local human populations; such areas may include recently described endemic foci in

Gansu, Qinghai, and Sichuan provinces, China, where surveys showed high rates of infection in domestic dogs.<sup>10,11</sup> The costs and benefits of this approach require further evaluation.

## ■ Polycystic Echinococcosis (*Echinococcus vogeli* and *Echinococcus oligarthrus*)

### AGENTS

*Echinococcus vogeli* was first described by Rausch and Bernstein<sup>120</sup> in 1972 from adult specimens recovered from a bush dog, *Speothos venaticus*, captured in the province of Esmeraldas, Ecuador. *Echinococcus oligarthrus* was first described by Diesing in 1863 from strobilate specimens recovered from a Brazilian puma. The larval cyst from the Brazilian agouti was named *Echinococcus cruzi* by Brumpt and Joyeux in 1924 but was subsequently shown to be that of *E. oligarthrus*.<sup>121</sup> *Echinococcus vogeli* is the principal cause of the polycystic form of echinococcosis in humans.<sup>122,123</sup> Both species utilize the same intermediate hosts (hystricognath rodents), in which the macroscopic appearance of the larval cysts is similar; however, differentiation of *E. vogeli* and *E. oligarthrus* (as well as other species of *Echinococcus*) can be made on the basis of the length and proportions of the rostellar hooks.<sup>124</sup> Because *E. oligarthrus* is known to infect humans, both are considered to be causes of PE. The metacestode of *E. vogeli* is fluid-filled, with a tendency to form multichambered conglomerates (polycystic); the predilection site in the intermediate host is the liver.<sup>122,123</sup> Endogenous proliferation and convolution of both germinal and laminated layers leads to the formation of secondary subdivisions of brood capsules and protoscolices.<sup>124,125</sup> The *E. oligarthrus* metacestode is similar; however, there is less subdivision into secondary chambers and the laminated layer is significantly thinner than that of *E. vogeli*. In lower animal hosts and in humans, *E. oligarthrus* metacestodes tend to be localized in the muscles or other extrahepatic sites (Fig. 114-11).

**FIGURE 114-11** Hydatid cyst of *Echinococcus oligarthrus* from intramuscular connective tissue of an infected rodent. (H&E; magnification about  $\times 1000$ ) (Courtesy of Dr. O. E. Sousa, Panama City, Panama.)

**FIGURE 114-12** Life cycle and principal and alternative hosts for *Echinococcus vogeli*.

### TRANSMISSION, EPIDEMIOLOGY, AND GEOGRAPHIC DISTRIBUTION

The life cycle of *E. vogeli* involves the bush dog and the paca, *Cuniculus paca*, as definitive and intermediate hosts, respectively (Fig. 114-12). Domestic dogs are also suitable definitive hosts. *Echinococcus vogeli* larvae have also been found in agoutis (*Dasyprocta* spp.) and spiny rats (*Proechimys* spp.).<sup>122,123</sup>

Very little is known about the circumstances associated with infection with this species. Bush dogs are rare and avoid human beings, and therefore probably play little role in direct exposure of humans. In endemic areas, human infections are probably acquired from the feces of domestic dogs that become infected when they ingest viscera of infected pacas; this practice has been reported commonly by patients.<sup>122,123</sup>

### *Echinococcus vogeli* and *Echinococcus oligarthrus*

- Countries in which cases of polycystic echinococcosis in humans have been documented.
- Countries in which *E. vogeli* and *E. oligarthrus* are known to occur in animal hosts.

Polycystic echinococcosis due to *E. vogeli* infection has been reported in most countries within the cestode's known range in neotropical America, including Costa Rica, Panama, Colombia, Argentina, Ecuador, Brazil, Bolivia, and Venezuela.<sup>122,123</sup> Some cases of PE are mistakenly assumed to be *E. granulosus* infection. The natural hosts of *E. vogeli* range throughout neotropical areas of Central and South America, and as local awareness and availability of diagnostic capability increase, it is probable that increasing numbers of cases will be recorded.

The infected bush dog, from which the specimens originally identified as *E. vogeli* were recovered,<sup>126</sup> was housed temporarily in the "children's area" of the Los Angeles Zoo adjacent to an enclosure that housed a variety of infant higher primates, including gorillas, gibbons, orangutans, and chimpanzees. The primates were exposed to eggs in feces of the infected canid and many of them became infected, with at least 15 of them dying of polycystic hydatid disease during the ensuing 10 years.<sup>127</sup> No infections in zoo employees or visitors were ever identified, but this incident illustrates the potential public health hazards associated with housing wild-caught animals that are potential hosts of *Echinococcus* spp.

*Echinococcus oligarthrus* is the only species of *Echinococcus* that characteristically uses wild felids as definitive hosts (Fig. 114-13). Naturally acquired infections have been demonstrated in the puma, the jaguarundi, the jaguar, the ocelot, the pampas cat, and Geoffroy's cat.<sup>1</sup> The larval forms of *E. oligarthrus* have been described in agoutis, pacas, spiny rats, and rabbits (*Sylvilagus floridianus*). Human infection with *E. oligarthrus* is extremely rare; only three human cases are documented.<sup>127-129</sup> Presumably, the remote behavior of the definitive hosts limits human exposure. The documented range of *E. oligarthrus* extends from northern Mexico to southern Argentina<sup>128</sup>; however, one of the definitive hosts of this species, the puma, ranges from Canada to Tierra del Fuego so that this cestode may be found through the Americas. The three confirmed cases of human disease caused by *E. oligarthrus* were reported from Venezuela and Brazil.<sup>127-129</sup>

## DISEASE

Approximately 80 human cases of PE have been recorded, mainly (more than 85%) from Brazil, Colombia, Ecuador, and Argentina.<sup>122,123,130,131</sup> Patients' ages at diagnosis have ranged from 6 to 78 years (median, 44), and the most common signs at presentation were hepatomegaly, palpable peritoneal masses, and jaundice. Polycystic echinococcosis has characteristics intermediate between the cystic and alveolar forms. Of cases in which the causative agent was speciated, the ratio of *E. vogeli* to *E. oligarthrus* was approximately 10:1. The primary localization of *E. vogeli* infections is the liver, but cysts often invade contiguous sites. In humans and other higher primates, the *E. vogeli* metacestode proliferates by means of a unique process after which extensive spread into the peritoneal cavity and other organs usually occurs.<sup>125</sup> Hepatomegaly or tumor-like masses in the liver have been typical findings. The lungs are involved in approximately 15% of cases. The clinical findings may be suggestive of malignancy, and the disease may lead to progressive deterioration of hepatic function, portal hypertension, and biliary cirrhosis. The prognosis for PE caused by *E. vogeli* is poor; approximately 14% of patients die from complications of biliary obstruction and portal hypertension. The three known cases of *E. oligarthrus* infection have involved the eyes (two cases) and the heart.<sup>127,128</sup>

Macroscopically, the larva of *E. vogeli* appears as a whitish-gray polycystic structure that contains a yellow fluid or gel.<sup>132</sup> The entire cyst may measure only 10 mm in diameter or may form vesicular aggregates that replace most of the liver. The protoscolex with its four circular suckers and rostellum with hooks can be seen in wet mount preparations and tissue sections. The large hooks are 38 to 46  $\mu\text{m}$  in length, and the small hooks measure 30 to 37  $\mu\text{m}$ . Microscopically, there are multiple vesicles, varying in size from a few millimeters to centimeters. The vesicles are partitioned by septa formed from the hyaline laminated membrane that is 8 to 65  $\mu\text{m}$  thick and stains intensely by the periodic acid-Schiff technique. The internal surface of the septa is lined with a germinal membrane that is 3 to 13  $\mu\text{m}$  thick and contains calcareous corpuscles.

**FIGURE 114-13** Life cycle and principal and alternative hosts for *Echinococcus oligarthrus*.

The brood capsules bud internally from the germinal epithelium. Externally, the cyst is surrounded by fibrous tissue, with only slight cellular infiltration. Portions of these cysts are frequently necrotic and mineralized, and the only remains of *Echinococcus* may be the hooks and calcareous corpuscles.

## DIAGNOSIS

The diagnosis of PE should be considered in patients who present with abdominal masses and who live or previously lived in rural Central or South American regions where the cestode agents are known to occur.<sup>122</sup> Radiologic imaging (radiograph, ultrasound, or CT) is very useful for demonstrating polycystic structures and diffuse mineralization in the liver or other sites (Fig. 114-14). Serologic tests are often, but not invariably, useful for confirming the diagnosis. Specific *E. vogeli* antigens may differentiate hydatid disease due to *E. vogeli* from that caused by *E. granulosus* but not from *E. multilocularis*; however, tests using *E. vogeli*-specific antigens are not widely available.<sup>133</sup>

## TREATMENT

Experience in the treatment of PE is limited. The principles of management of CE and AE also apply to PE. Because the lesions are so extensive, surgical resection may be difficult and usually incomplete. A combination of surgery with albendazole treatment is most likely to be successful.<sup>122</sup> Approximately 40% of patients with *E. vogeli* PE improved (reduction or disappearance of cysts for 10 to 30 months) after receiving albendazole 10 mg/kg/day for different lengths of time from weeks to months.<sup>122,130</sup>

**FIGURE 114-14** Abdominal computed tomography scans showing multiple *Echinococcus vogeli* larvae (polycystic echinococcosis). The lesions are hypodense, round or oval, and scattered in the liver, spleen, and abdominal cavity. (Courtesy of Dr. V. G. Meneghelli, São Paulo, Brazil.)

## PREVENTION AND CONTROL

In regions where *E. vogeli* and *E. oligarthrus* are enzootic in sylvatic cycles, emphasis should be placed on personal preventive measures, including avoiding contact with wild canids and felids. Raw viscera of animals killed in hunting should not be given to dogs and cats. Control of pet dogs and cats must be practiced to prevent them from preying on rodents and thereby becoming infected. For dogs or cats that cannot be controlled and that habitually prey on local rodents, prophylactic treatment with praziquantel 5 mg/kg body weight can be given. People living in areas where *E. vogeli* and *E. oligarthrus* are enzootic should be educated about the potential dangers, to promote better personal hygiene and sanitation and to motivate them to take effective measures to prevent their pets from becoming infected.

No experiences have been reported on active intervention to limit transmission in any area.

# Taenia and Other Tapeworms

MURRAY WITTNER  
HERBERT B. TANOWITZ

## ■ Taeniasis

### INTRODUCTION

The pork tapeworm, *Taenia solium*, and the beef tapeworm, *Taenia saginata*, are parasites of man that have been known since ancient Greece.<sup>1</sup> Taeniasis occurs whenever infected insufficiently cooked beef or pork is consumed.<sup>2,3</sup> However, it was not until 1782 that Goeze differentiated the two species. The larval stage was clearly described by Aristotle and Aristophanes from the tongue of hogs, but it remained for Leukart (1856) and Kuchenmeister (1855) to prove that human infection with the adult worm resulted from eating pork containing viable larvae.<sup>1,2</sup>

### AGENT

*Taenia saginata* adult worms vary in size from 4 to 12 m and may be composed of 1000 to 2000 proglottids. When mature proglottids become gravid, the testes, ovaries, and other reproductive organs degenerate and are replaced by the enlarging egg-filled uterus (Fig. 115-1). The scolex of *T. saginata*

**FIGURE 115-1** *Taenia solium* proglottid. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

**FIGURE 115-2** *Taenia saginata* scolex. Note the four suckers and no hooks. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

is distinctive, being approximately 1.5 to 2.0 mm wide and possessing four simple sucking disks, and is “unarmed” (i.e., without hooklets; Fig. 115-2). In contrast, *T. solium* is somewhat smaller, varying from 2 to 8 m, with a total of approximately 1000 proglottids. The scolex possesses a well-developed crown or rostellum upon which is a double row of hooklets—that is, it is “armed”<sup>3</sup> (Fig. 115-3).

These tapeworms generally are attached by their scolex to the jejunal mucosa. The strobila, which is not fixed in position, moves frequently, even against the peristaltic stream. Gravid proglottids contain thousands of spherical thick-walled eggs, which are radially striated and contain a mature six-hooked (hexacanth) embryo called an oncosphere. The eggs are 30 to 40  $\mu$ m in diameter and are similar and essentially indistinguishable in all members of the genus (Fig. 115-4). Cattle or hogs become infected by ingesting mature eggs contaminating low-lying pastures or barnyards. In endemic areas, pigs acquire the infection rapidly since they actively seek and eat human stools at defecation sites or latrines.<sup>4</sup> Hatching is initiated by the action of gastric juice,

**FIGURE 115-3** *Taenia solium* scolex. Four suckers and hooks are seen. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

**FIGURE 115-4** *Taenia* ovum. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

intestinal enzymes, and bile on the eggs. Liberated embryos penetrate the intestinal mucosa of cattle or hogs, enter the circulation, and are transported throughout the body. *Taenia saginata* oncospheres produce excretory-secretory peptidases, including serine and cysteine endopeptidases, and aminopeptidase, which may play a role in invasion of the intestinal mucosa.<sup>5</sup> Larval encystment usually occurs in striated muscle and the central nervous system, and within 8 to 11 weeks the larvae, termed *Cysticercus solium* (*cellulosae*) in hogs and *Cysticercus bovis* in cattle, become infectious. Cysticerci are ellipsoid, translucent bladder-like cysts in which an inverted scolex has developed. In humans who ingest infective eggs of *T. solium*, cysticerci develop similarly.

On consumption of infected raw or inadequately cooked beef or pork, the cysticercus is activated by gastric juices and bile salts, which stimulate evagination of the scolex. It then attaches to the jejunal wall, and *T. solium* becomes a mature tapeworm in 5 to 12 weeks, whereas it takes approximately 10 to 12 weeks for *T. saginata*. The adult tapeworm may live for 25 years or more.<sup>3</sup> Molecular approaches in the study of *Taenia* have led to a number of potentially important findings that may aid in the diagnosis and therapy of *Taenia* infections.<sup>6–8</sup>

## EPIDEMIOLOGY

Both infections have worldwide distribution, but there are no reliable statistics with regard to their prevalence. *Taenia saginata* is commonly found in the United States, Europe, South America, and Africa. *Taenia solium* is common in Mexico, Central and South America, Africa, Eastern Europe, China, Pakistan, and India.<sup>9–12</sup> Additional discussion of the epidemiology of *T. solium* and cysticercosis can be found in Chapter 113.

Humans are the obligatory definitive host for both of these tapeworms. Whereas infection with the pork tapeworm is uncommon in the United States, cysticercosis of hogs is not uncommon. Currently, *T. solium* infections are reported from a relatively small number of nations, especially Mexico, Central and South America, the Balkan countries, East Africa, India, China, and Indonesia. However, the extent of the

endemicity of the infection is largely unknown. For example, it was reported that more than 13% of the pigs examined in abattoirs in Tanzania had cysticercosis,<sup>13</sup> and wherever adult pork tapeworm infection is encountered, human cysticercosis is not unusual.

A third form of human *Taenia* infection is due to *Taenia asiatica*, which has been reported in Taiwan, Korea, Indonesia, Vietnam, and China. Molecular approaches indicate that *T. asiatica* is more closely related to *T. saginata* than to *T. solium*.<sup>14,15</sup>

*Taenia saginata* infection occurs among those who prefer to eat raw or insufficiently cooked beef. *Taenia saginata* infection is a “true zoonosis” in which man is the mandatory definitive host who disseminates the infection to bovine intermediate hosts. More commonly, transmission occurs through fecal contamination of low-lying grazing lands, cattle feed, and also by birds and flies.<sup>16</sup> A solid acquired immunity to the oncosphere and postoncosphere stage develops in intermediate hosts (pigs and cattle) following ingestion of relatively few eggs and is maintained for months to years without further exposure. This limits the number of cysts in the host with regard to subsequent exposures. Low and high temperature extremes (–70° to +40°C) as well as desiccation are important environmental factors that affect survival of the ova. Dipteran flies may also increase the dispersion of eggs in the environment.<sup>16</sup>

## DISEASE

Following the ingestion of viable metacestodes (cysticerci) in improperly cooked or raw beef or pork, the scolex evaginates and attaches to the upper jejunum by its well-developed holdfast organs, and strobilation occurs. Infection with adult tapeworms causes few pathologic changes. However, intestinal mucosal biopsies in patients harboring *T. saginata* have shown a minimal inflammatory reaction, suggesting that the worms can have an “irritative” effect, perhaps causing clinical symptoms.

Most people who harbor *T. solium* or *T. saginata* are either asymptomatic or have mild to moderate complaints. Occasionally, these infections can result in serious, life-threatening illness from intestinal,<sup>17</sup> biliary, or pancreatic obstruction (Fig. 115-5). Rarely, an individual may regurgitate

**FIGURE 115-5** *Taenia* proglottid in intestine.

# Beef Tapeworm

## *Taenia saginata*

and aspirate a proglottid. The most frequently reported sign of adult *T. saginata* infection is spontaneous egress of proglottids per rectum. Infection with either species may be associated with abdominal pain, nausea, weakness, loss of appetite, increased appetite, headache, constipation, dizziness, diarrhea, pruritis ani, and hyperexcitability. Abdominal pain and nausea are reported to be more common in the morning and characteristically relieved by small amounts of food. Children are more frequently symptomatic than adults. Eosinophilia is often present and rarely levels can rise to more than 50% but are usually 5 to 15%. Serum immunoglobulin E (IgE) levels may be increased.

### DIAGNOSIS

The presence of *Taenia* eggs in the stool is not sufficient to differentiate species; a gravid proglottid must be obtained for this purpose.<sup>18</sup> Identification of proglottids is done by

pressing the segment between two glass microscope slides and counting the main lateral branches on one side of the uterus. *Taenia solium* has fewer primary branches, usually 7 to 13 on each side; *T. saginata* usually has more than 15 lateral primary branches per side<sup>18</sup> (Fig. 115-6). Stool examination may be unrewarding in the case of *T. saginata* infection since gravid proglottids often emerge spontaneously per anus, depositing eggs on the perianal and perineal region. Thus, anal swabs, such as the "Scotch tape" method, as usually done for the diagnosis of pinworm (see Chapter 107), are recommended to recover the ova. It has been demonstrated that using an electrolyte-polyethyleneglycol solution as a purge enhances the recovery of the scolex and proglottids, which could aid in species identification.<sup>19</sup>

In recent years, a number of immunodiagnostic and molecular approaches have been developed for the diagnosis of taeniasis.<sup>8,10,20-22</sup> These tests have included the detection of coproantigens, copro-DNA, and serum antibodies to

**FIGURE 115-6** A, *Taenia solium* proglottid (India ink-stained). B, *Taenia saginata* proglottid (India ink-stained).

adult-stage antigens. Some of these methods were shown to be highly sensitive and specific. A multiplex polymerase chain reaction<sup>20</sup> has been developed for use on both feces and parasites that can differentiate among the *Taenia* species and is based on cestode mitochondrial DNA. This method may also prove to be useful for molecular epidemiology studies.

### TREATMENT AND PROGNOSIS

The treatment of both tapeworm infections is similar. Praziquantel can be administered as a single dose of 10 to 20 mg/kg.<sup>23</sup> For the treatment of *T. solium*, precautions should be taken to prevent autoinfection or dissemination to others. Thus, drugs that induce vomiting should be avoided since

retrograde peristalsis may raise gravid proglottids into the gastroduodenal area, resulting in their digestion followed by egg hatching and penetration of the intestine, leading to disseminated cysticercosis. In addition, since praziquantel kills the worm (Fig. 115-7) but does not inactivate the eggs released from the disintegrating gravid segments, cysticercosis is theoretically possible following treatment. It is also unknown whether larvae released from eggs in the colon are capable of penetrating the intestinal wall. However, no cases of cysticercosis have been reported by this mechanism. Post-treatment follow-up stool examination should be performed after approximately 5 weeks in the case of *T. solium* and 3 months for *T. saginata* infections. The prognosis of treated taeniasis is excellent.

### PREVENTION AND CONTROL

Education is an important aspect of the prevention of taeniasis.<sup>11</sup> Beef and pork tapeworm infection can be prevented by adequate cooking or freezing of beef and pork. *Cysticercus solium* (*cellulosae*) is killed by moderate temperatures of 65°C (150°F) or if the pork is frozen at -20°C (-38°F) for at least 12 hours. Pickling in brine or salting pork is not always an adequate method. *Cysticercus bovis* is killed by thorough cooking at 56°C (131°F) or freezing at -10°C for 5 days. Pickling of beef in 25% brine for 5 or 6 days is said to render the beef safe. Treatment of all infected people would eliminate the source of soil and sewage pollution with *Taenia* eggs and therefore reduce porcine and bovine infection. Meat inspection would help reduce transmission to humans who fail to properly prepare meat. Investigations are under way to develop an effective vaccine against cysticercosis in pigs. Encouraging results have been obtained.<sup>24</sup>

### TAENIA CRASSICEPS

*Taenia crassiceps* is a tapeworm of canids that is rarely transmitted to humans by the oral-fecal route. Since humans are not the usual hosts, it presents as a cysticercus in the brain, eye, or subcutaneous tissue.<sup>25-28</sup> Medical therapy has been disappointing. Interestingly, Chuck and colleagues<sup>29</sup> reported a case of subretinal *T. crassiceps* managed by surgery (Plate 115-1).

## Diphyllobothriasis

### INTRODUCTION

*Diphyllobothrium latum* is a frequent human intestinal parasite in many areas where uncooked freshwater fish is consumed.<sup>30-34</sup>

### AGENT

The distinction between *D. latum*, the broad or fish tapeworm, and *Taenia* appears to have been well-known to medieval physicians, and it was the earliest pseudophyllidean tapeworm to be scientifically recognized (Linnaeus, 1758).<sup>1</sup>

The life cycle of *D. latum* requires three hosts: (1) The definitive hosts are humans and fish-eating carnivores, (2) the first intermediate hosts are a large number of copepod species (crustaceans), and (3) the second intermediate hosts are freshwater fish. It is a large tapeworm, often consisting

**FIGURE 115-7** Scanning electron microscopy of *Taenia solium* scolex, showing effect of praziquantel. (From Thomas H, Andrews P, Mehlhorn H: New results on the effect of praziquantel in experimental cysticercosis. Am J Trop Med Hyg 31:803-810, 1982.)

Vague abd. pain  
bloating, diarrhea.  
Rarely obstruction,  
megaloblastic anemia

of 3000 to 4000 segments or proglottids measuring from 3 to 12 m, that inhabits the ileum and jejunum. It possesses a scolex that is characteristically elongate or spoon-shaped with a ventral and dorsal sucking groove or bothrium (Fig. 115-8). Most of this tapeworm consists of mature or maturing proglottids. Egg production usually takes place in

many proglottids simultaneously over a relatively extended period. The mature proglottid is broader than it is long and contains both male and female reproductive organs. In the center of the mature proglottid is a characteristic dark rosette—that is, the egg-filled uterus that aids in its recognition (Fig. 115-9). The uterus leads to a muscular

**FIGURE 115-8** *Diphyllbothrium latum*. Immature proglottids and scolex. The scolex bears grooves. (From Zaiman H [ed]: A Pictorial Presentation of Parasites. Valley City, ND, Mercy Hospital, 1900–1982.)

uterine pore on the ventral surface of the segment through which the eggs pass into the feces. Typically, proglottids do not break off and migrate out of the body, as occurs in taeniasis, but upward of a million eggs per day are extruded into the small intestinal lumen by contractions of the uterine pore. Spent proglottids eventually disintegrate and pass out of the body. Occasionally, a long chain of proglottids is passed with the stool.<sup>18</sup>

The characteristic light-yellow eggs are 42 to 50  $\mu\text{m} \times$  59 to 75  $\mu\text{m}$ , with an operculum or lid at one end and a characteristic tiny knob at the abopercular end (Fig. 115-10).<sup>7</sup> In fresh water, the unembryonated egg requires approximately 10 days to 2 weeks to mature at 15°C to 25°C. After the operculum opens, a ciliated hexacanth, or six-hooked, embryo (coracidium) emerges; the swimming embryo must be ingested within 6 to 12 hours by one of several crustacean species of copepods or perish (*Cyclops* sp. and *Diaptomus* sp.). The larva penetrates the midgut and enters the hemocoel of

**FIGURE 115-10** *Diphyllbothrium latum*. Ovum.

the copepod and in 10 to 21 days transforms into an elongated proceroid larva, reaching approximately 0.5 mm in length. It remains in the copepod until ingested by one of many species of small freshwater plankton-eating fish (second intermediate host). The proceroid larva next makes its way through the tissues of the fish and settles between the muscle fibers, where it transforms into a plerocercoid (sparganum) larva. The latter has the characteristic rudiments of a scolex but is unsegmented. Next, these fish are eaten by larger carnivorous fish, such as rainbow trout, walleyed pike, or the burbot (paratenic or transport hosts). The plerocercoid larvae reinvade the muscles of these fish and if consumed raw or inadequately cooked by a suitable host (i.e., humans), the larva attaches to the wall of the small intestine and becomes a mature tapeworm in approximately 5 or 6 weeks.

Other adult diphyllbothriid species, normally parasites of fish-eating mammals, have occasionally been found in humans, dogs, and cats in China: *Diplogonoporus grandis*, a whale parasite, found on rare occasions in humans in Japan; *Diphyllbothrium dendriticum*, found commonly in piscivorous birds and mammals in the Northern Hemisphere; and *Diphyllbothrium pacificum*, found in seals (its natural host) and marine fish (its intermediate host) in Peru and Chile.<sup>35</sup>

## EPIDEMIOLOGY

*Diphyllbothrium latum* biotypes are mostly shallow freshwater littorals with vegetation favoring the development of copepods and fish. Infection with this parasite is most prevalent in areas of the North Temperate and sub-Arctic zones, where freshwater fish are commonly consumed.<sup>36</sup>

The prevalence of diphyllbothriasis has decreased in many areas of the world. The estimated worldwide prevalence is approximately 9 to 10 million people. In North America, highly endemic foci have been found among Native Americans in Alaska and Canada and particularly in the smaller lakes of the Great Lakes region. In the United States, fish from the lakes of the north-central region, especially Minnesota and Michigan, and from Florida and California are found infected. In the highly endemic regions of Finnish and Russian Karelia, prevalence has ranged from 25% to 100%.<sup>33</sup> In North America, there has been a decline in human cases, whereas in South America there have been increased

**FIGURE 115-9** *Diphyllbothrium latum*. Proglottid. Note the rosette shape of the uterus. (From Zaiman H [ed]: A Pictorial Presentation of Parasites. Valley City, ND, Mercy Hospital, 1900–1982. Courtesy of Dr. J. F. Mueller.)

reports from fish, especially salmonids. Transmission has been brought under control in Western Europe, and only a few cases occur in Finland, where nearly 20% of the country was infected in the 1950s. In addition, areas of Sweden, France, Switzerland, northwestern Russia, the Danube and lower Volga basins, and the lake regions of northern Italy and Switzerland contain infected fish. Freshwater lakes in many areas of Africa, including Madagascar, and in the People's Republic of China, Taiwan, Japan, Turkey, Ireland, Israel, Papua New Guinea, Australia, the Philippines, Argentina, and southern Chile may contain infected fish. Humans are the primary definitive host and most important reservoir of infection. Other definitive and reservoir hosts are fish-eating mammals, such as the fox, mink, bear, domestic and wild cat, dog, pig, walrus, and seal. Secondary intermediate hosts are many species of brackish and freshwater fish, including anadromous fish that spawn in fresh water (e.g., salmon). Salmon has been the cause of the transmission of this parasite in Japan and the West Coast of the United States where sushi has been prepared with infected salmon.<sup>34</sup> Important factors that have contributed to the spread of infection are the emigration of infected populations, the construction of dams and other water projects, and the practice of allowing untreated sewage to enter freshwater lakes. Cases of diphyllbothriasis sometimes occur outside endemic areas as a result of infected fish being shipped under refrigeration to be sold in markets in large urban centers.

Eating raw, insufficiently cooked, or lightly pickled fish or fresh roe is common among many ethnic groups, which consider it a delicacy. For example, for many years in New York City, infected freshwater fish, transported on ice, was the main source of this tapeworm infection among Jewish housewives who made gefilte fish. Typically, small amounts of raw fish were sampled in order to season this ethnic delicacy to taste. In northern Minnesota and Michigan, where large numbers of people of Scandinavian background live, raw and pickled fish are still eaten and infection with *D. latum* is not uncommon. Women who taste raw fish while preparing it for cooking also have higher prevalence rates. There are other diphyllbothriids that cause disease. *Diphyllbothrium pacificum* has been reported from Japan and is endemic in coastal areas of Peru. Unlike *D. latum*, infection with this parasite is acquired from eating marine fish that have been prepared in lime juice (e.g., ceviche). *Diplogonoporus grandis*, another member of this group, is found in Japan and thought to be acquired by consumption of raw anchovies and sardines. Other species of *Diphyllbothrium*, such as *Diphyllbothrium dendriticum*, *Diphyllbothrium klebanovskii*, *Diphyllbothrium cordatum*, *Diphyllbothrium dalliae*, *Diphyllbothrium ursi*, and *Diphyllbothrium nihonkaiense*, are found as occasional human parasites.<sup>35</sup> Restriction fragment length polymorphism studies between *D. nihonkaiense* and *D. latum* recombinant DNA failed to show any variations, suggesting their very close identity.<sup>37</sup> Their usual definitive hosts are various marine mammals, carnivores, or marine birds.

## DISEASE

Harboring this large tapeworm is usually associated with surprisingly few symptoms or pathologic changes in the intestinal mucosa. Often, the infection is first recognized in an

asymptomatic patient as a result of a stool examination carried out for other reasons. However, some patients complain of vague abdominal pain and others describe the sensation that "something is moving inside." Others describe bloating, sore tongue, sore gums, allergic symptoms, headache, hunger pains, loss of appetite, or increased appetite. Rarely, mechanical intestinal obstruction may occur as a result of several worms becoming entangled. Diarrhea may also occur. Almost all patients become aware of the infection when spontaneously passing a large section of the spent proglottids; most often this startling event brings the patient to the office or clinic. Unlike the proglottids of *T. saginata*, those of *D. latum* do not spontaneously crawl through the anus.<sup>38</sup>

In a very small number of patients, a megaloblastic pernicious anemia has been shown to be caused by infection with *D. latum* ("bothriocephalus anemia" or "tapeworm anemia"). When fully manifest, this anemia is a hyperchromic, macrocytic, megaloblastic anemia with thrombocytopenia and mild leukopenia. The development of pernicious anemia is usually associated with high attachment of the tapeworm within 145 cm of the mouth. In this situation, more than 80% of vitamin B<sub>12</sub> is absorbed by the worm, with a differential absorption pattern of 1000:1 in favor of the worm. For unknown reasons, the anemia associated with diphyllbothriasis is most frequently encountered in Scandinavia. In the United States, people of Scandinavian background are most frequently affected.

Approximately 40% of people harboring the worm have reduced serum vitamin B<sub>12</sub> levels, but fewer than 2% develop anemia. Neurologic lesions due to vitamin B<sub>12</sub> deficiency include subacute combined degeneration of the dorsal and lateral columns and peripheral nerve degeneration. In the spinal cord, the posterior and lateral columns are involved. The anemia and neurologic manifestations respond to vitamin B<sub>12</sub> and do not recur after the worm has been expelled.

## DIAGNOSIS

The infection can be diagnosed readily by finding characteristic ova in the feces (see Fig. 115-10).<sup>18</sup> Concentration methods are usually unnecessary since the numbers of eggs present are often so great that direct examination of a small amount of the patient's feces in a drop of saline is usually sufficient. Molecular methods have been explored for the diagnosis of *Diphyllbothrium* sp.<sup>37</sup> Tapeworm-induced anemia may be associated with free hydrochloric acid in the gastric juice; in contrast, pernicious anemia is associated with achlorhydria. There is no reliable serologic test to aid in diagnosis. It is not uncommon to find an eosinophilia of 5% to 10% in patients with *D. latum* infection accompanied by a minimal leukocytosis.

## TREATMENT AND PROGNOSIS

The treatment of choice is praziquantel, which is administered as a single dose of 5 to 10 mg/kg for both adults and children.<sup>23,39</sup> Niclosamide is given as a 2-g dose once for adults and 50 mg/kg for children. The prognosis for treated individuals is excellent.

## PREVENTION AND CONTROL

Careful cooking of freshwater fish would eliminate all possibility of human infection. The sale of fish originating in heavily infected lakes should be regulated because freezing at  $-10^{\circ}\text{C}$  for 24 hours suffices to kill the plerocercoid larva. In the United States, smoked salmon is usually brined before smoking and is not considered a source of infection. Other control measures include the education of cooks regarding the sampling of raw fish during preparation. In addition, sanitary sewage disposal rather than the dumping of raw sewage into freshwater lakes also would prevent viable eggs from contaminating various intermediate hosts. In highly endemic areas, human infection should be detected by survey and treated.

## Hymenolepiasis

### INTRODUCTION

There are two species of *Hymenolepis* that infect humans: *Hymenolepis nana* and *Hymenolepis diminuta*. Both are cosmopolitan in their distribution, but the former is more common in warmer climates and the latter is a common parasite of rats and mice and only occasionally infects humans.<sup>40,41</sup>

### AGENT

The adult *H. nana* is approximately 0.5 cm long and is found attached to the mucosa of the ileum by a scolex that has four suckers and a retractable, armed rostellum (Fig. 115-11). The entire worm usually consists of a scolex and approximately 200 proglottids. The uterus in a gravid proglottid contains approximately 100 to 200 mature eggs that are 30 to 60  $\mu\text{m}$  in diameter (Fig. 115-12).<sup>17,40,41</sup> An intermediate host is not required to complete the life cycle. The eggs are passed in the feces and ingested by a new human or the same host (autoinfection). The embryo hatches in the small intestine and penetrates a villus, where it becomes a cysticercoid larva (Fig. 115-13). Upon maturation, in 3 or 4 days, it emerges from the tissue and attaches to the intestinal mucosa

**FIGURE 115-12** *Hymenolepis nana* ovum. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

by its scolex. In 2 or 3 weeks, the new worm is producing eggs. Hyperinfection can occur when eggs liberated in the small intestine hatch and immediately penetrate a villus to undergo a new cycle. As a result of hyperinfection, children may harbor many hundreds or even thousands of adult worms. The entire life history from ingestion of the egg to adulthood requires approximately 10 days to 2 weeks. Eggs are first seen in the stools in approximately 25 to 30 days. *Hymenolepis nana* is regarded as a hand-to-mouth infection and, as a result, is most frequently encountered in children, institutions, and families. Certain strains of *H. nana* may undergo larval development in various fleas and mealworms, and these larvae have developed to adults in mice; human infection with murine strains is unusual.

The closely related species, *H. diminuta*, which commonly parasitizes the rat and mouse, infrequently infects humans.<sup>41</sup> Most of the more than 200 reported human infections have been in children younger than 3 years of age. The adult worm is 10 to 60 cm  $\times$  3 to 5 mm and possesses a club-shaped scolex that has a rudimentary apical unarmed rostellum with four small suckers. The ova are spherical and 60 to 86  $\mu\text{m}$  in diameter.<sup>18</sup>

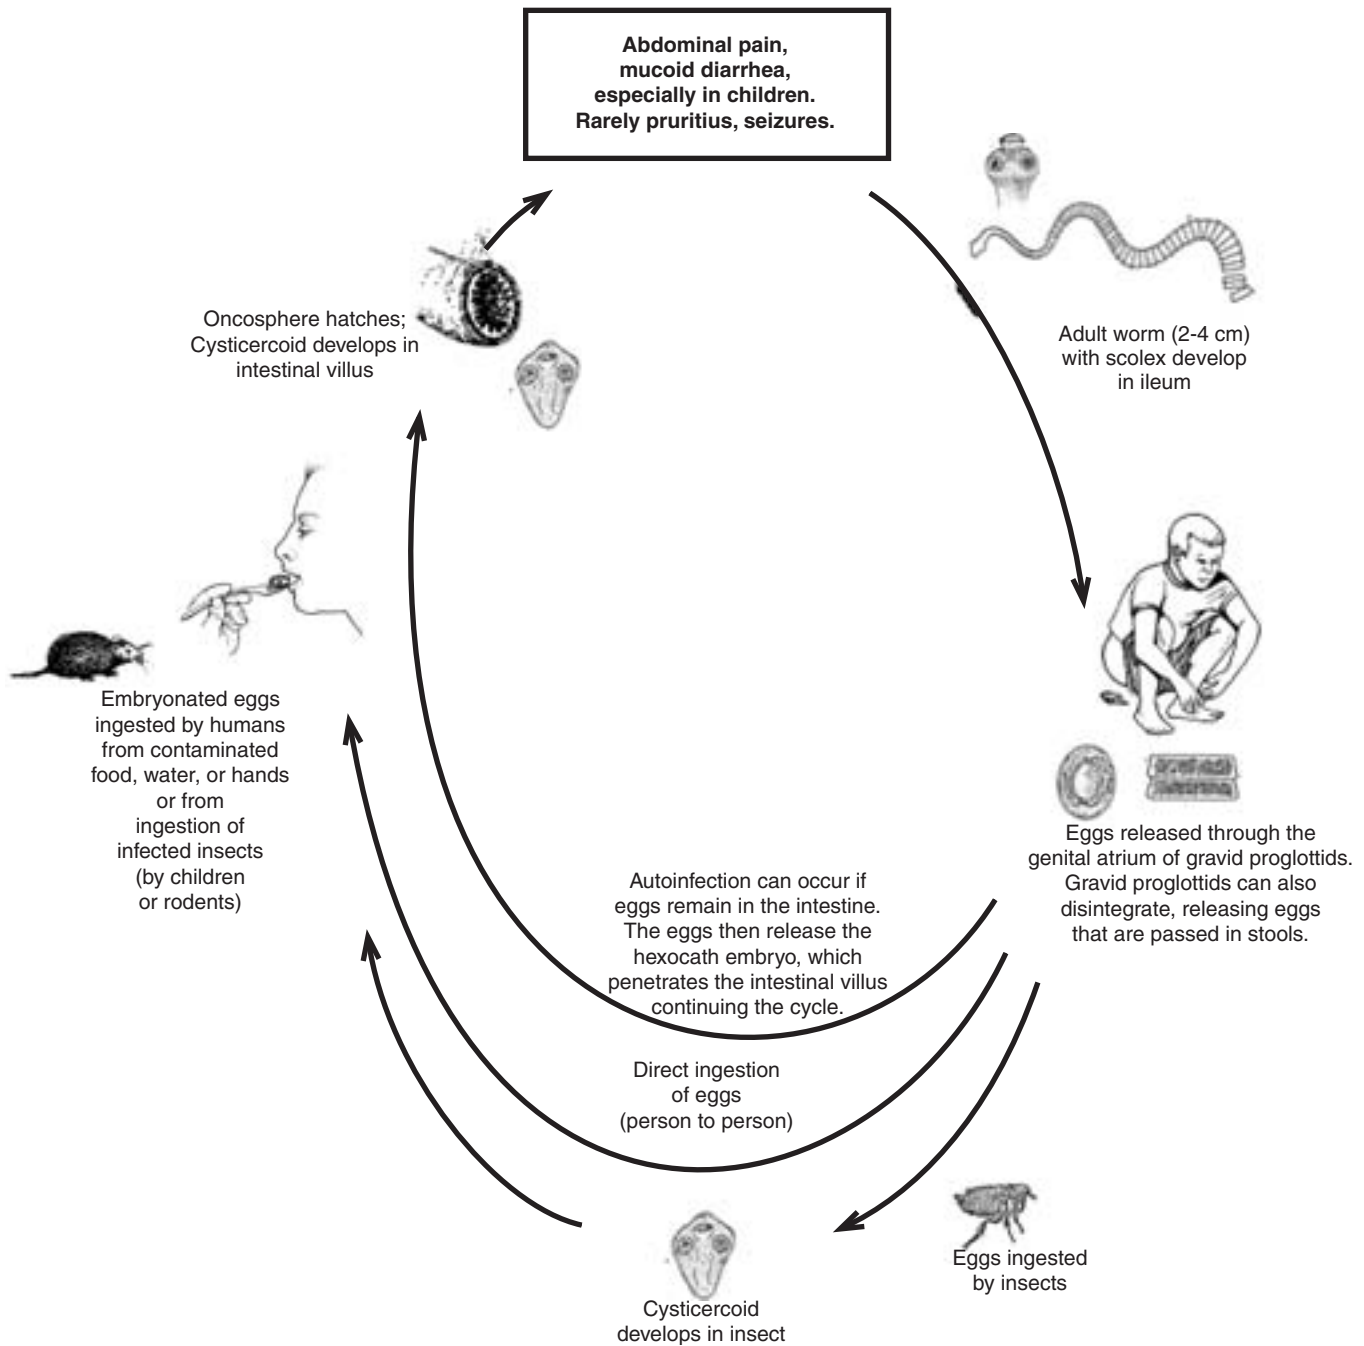

**FIGURE 115-11** *Hymenolepis nana* scolex and proglottids. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

**FIGURE 115-13** *Hymenolepis nana* cysticercoid stage in the small intestine. (Original photo by B. Gueft, MD, from a specimen by M. Yoelli, MD. From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

## *Hymenolepis nana*

In contrast to the eggs of *H. nana*, there are no polar filaments. Development of this tapeworm requires an intermediate host. Presumably, infected rat fleas (*Nosopsyllus* and *Xenopsylla*) and mealworms (*Tenebrio*) are accidentally ingested, and the mature adult develops in approximately 3 weeks. Cockroaches may also serve as intermediate hosts and become infected by ingesting eggs passed in rodent feces. A related helminth in rodents, *Rhodentolepis* (= *Hymenolepis*) *microstoma*, has been reported in humans.<sup>42</sup> Molecular approaches have been applied to the epidemiology and diagnosis of *Hymenolepis* infections.<sup>43,44</sup> Studies indicate a role for the immune system in the expulsion of this parasite from rodent hosts.<sup>45-47</sup>

### EPIDEMIOLOGY

The dwarf tapeworm, *H. nana*, is found in most warm regions of the world. It is the most common cestode infection in the southeastern United States and Latin America, and it is common throughout southern Europe, Russia and the former Soviet republics, and the Indian subcontinent.<sup>41,48-50</sup>

### DISEASE

Young children are particularly troubled with *H. nana* infections, especially when many worms are present.<sup>50</sup>

These patients commonly have loose bowel movements or occasionally frank diarrhea with mucus but no blood. Diffuse, persistent abdominal pain is the most common complaint. Pruritus ani and nasi are occasionally encountered. Many children have sleep and behavioral disturbances that clear after successful therapy. Serious neurologic disturbances such as seizures have been reported. Many patients with hymenolepiasis have a moderate eosinophilia of 5% to 10% and skin eruptions.<sup>51</sup> A patient with acquired immunodeficiency syndrome (AIDS) was diagnosed with invasive lethal infection with *H. nana*.<sup>52</sup>

## DIAGNOSIS

The diagnosis of hymenolepiasis rests on finding the characteristic ova by stool examination. Stools of the entire family must be checked before therapy is initiated because other members of a household are commonly infected, and they must also be treated for therapy to be successful. As in all tapeworm infections, post-treatment stool examinations should be done after 5 weeks and again after 3 months.<sup>1-3</sup>

## TREATMENT AND PROGNOSIS

Praziquantel is the drug of choice for the treatment of hymenolepiasis and is highly effective in a single dose of 15 mg/kg. It not only eliminates adult worms but also, unlike other anthelmintics, is efficiently absorbed and kills the larval stages (cysticercoids) in the submucosa.<sup>2</sup> Praziquantel has not been approved for this indication by the U.S. Food and Drug Administration. Treated individuals have an excellent prognosis.

## PREVENTION AND CONTROL

This infection is a hand-to-mouth disease and therefore extremely difficult to control. Education in hygiene is probably the only practical way to reduce the incidence.

## ■ Dipylidiasis

### INTRODUCTION

The dog tapeworm, *Dipylidium caninum*, is also a frequent parasite of cats and wild carnivores worldwide. It is an occasional parasite of the small intestine of humans.

### AGENT

The adult worm is approximately 15 to 20 cm long and usually has approximately 60 to 175 proglottids. The scolex is characteristic, being rhomboid with four oval suckers and an armed retractable conical rostellum containing 30 to 150 thorn-shaped hooks arranged in transverse rows (Fig. 115-14). The proglottids have a double set of reproductive organs with genital pores midway on each lateral margin (Fig. 115-15). The gravid proglottids are packed with 15 to 25 eggs. Each egg is 35 to 60  $\mu\text{m}$  in diameter and contains an oncosphere with six hooklets. The strobila can migrate several inches per hour and pass out of the anus spontaneously or with the feces. Eggs are expelled by contraction or disintegration of the proglottid.<sup>53</sup>

**FIGURE 115-14** *Dipylidium caninum* scolex. Three of the four suckers and the retracted armed rostellum can be seen. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

### EPIDEMIOLOGY

Most infections occur in children younger than 8 years old as well as infants younger than 6 months of age.<sup>54-57</sup> The ova of *Dipylidium* are ingested by the larval dog or cat flea, in which they become cysticercoid larvae. Infection occurs following accidental ingestion of the infected flea.

### DISEASE

Infection is often asymptomatic, although some children have intestinal disturbances, including abdominal pain and diarrhea (Fig. 115-16).<sup>54-57</sup> Allergic manifestations such as urticaria and pruritus ani have been reported; intestinal obstruction has been a rare complication.<sup>1,2</sup>

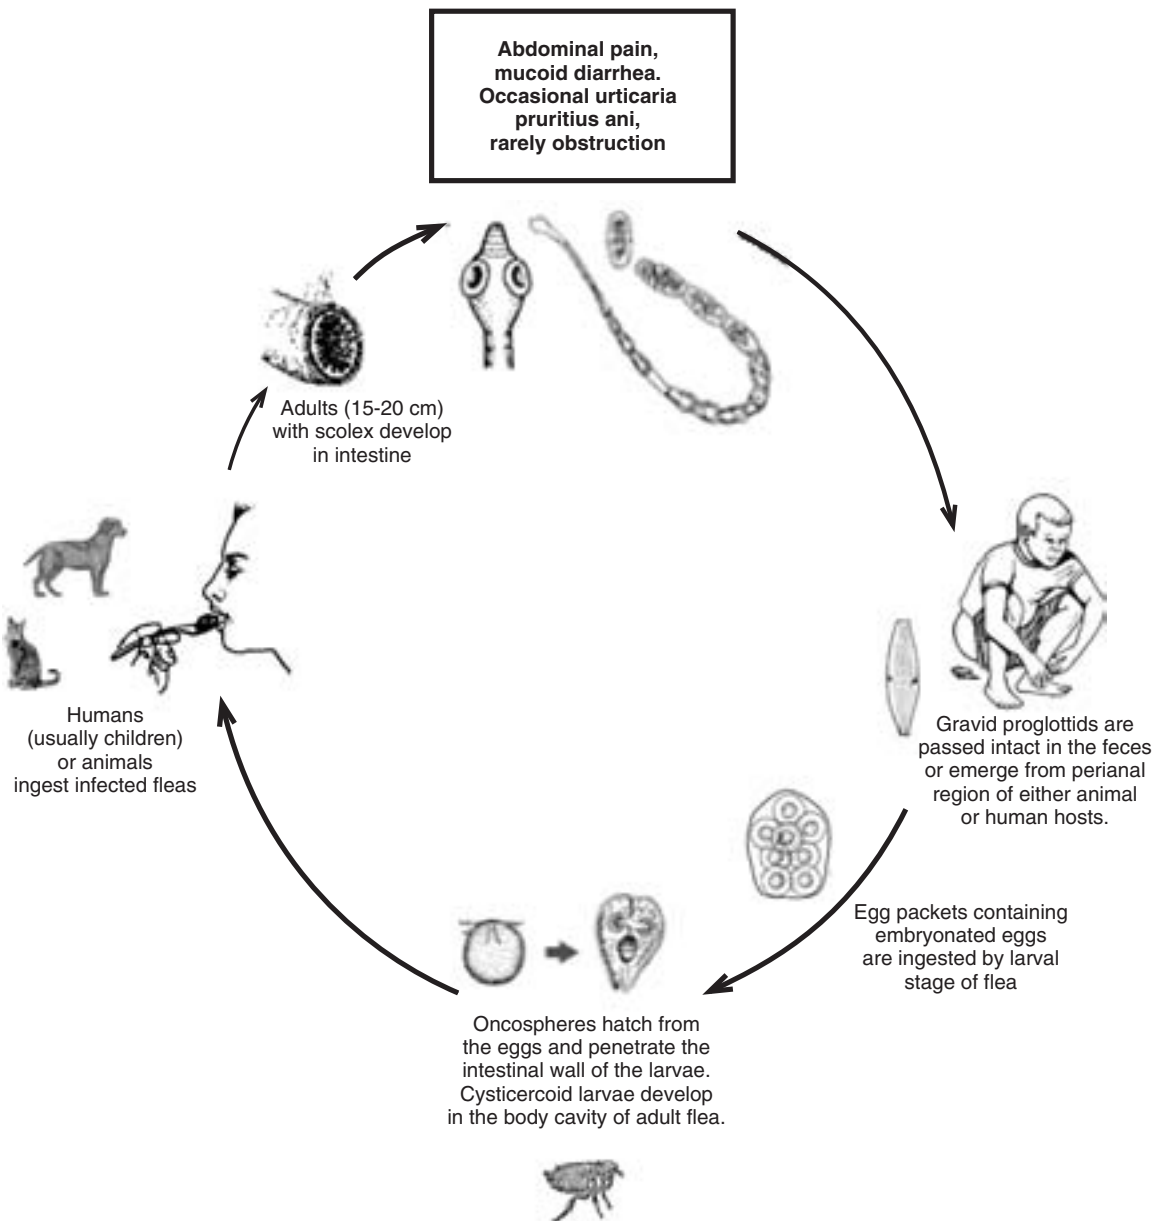

### TREATMENT AND PREVENTION

Treatment is with 5 to 10 mg/kg of praziquantel once for both adults and children. An alternative therapy is 2 g of niclosamide once for adults and 25 mg/kg once for children. Children should not be allowed to fondle and

**FIGURE 115-15** *Dipylidium caninum* proglottid. Note the two genital pores and the massing of the ova. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

## *Dipylidium caninum*

kiss dogs and cats. Periodic treatment of pets for tapeworm infection and periodic use of insecticides to kill ectoparasites will control the spread of this infection.

### ■ Sparganosis

#### INTRODUCTION

Sparganosis is an uncommon parasitic infection usually caused by the migration of larval tapeworms of the genus *Spirometra*.

#### AGENT

Human sparganosis may occur following ingestion of species of *Cyclops* that are infected with the procercoid larva

of various pseudophyllidean tapeworms of the species *Spirometra*.<sup>1,58</sup> The proceroid penetrates the intestinal wall and migrates to various sites, including subcutaneous tissues, the central nervous system, and muscle, where they develop to second-stage larvae or plerocercoids. This condition is called sparganosis. Ingestion, either deliberately or accidentally, of infected uncooked flesh of an amphibian, reptile,<sup>59</sup> bird, or mammal harboring plerocercoid larvae may also be a source of infection. Spargana also develop in hogs and it has been shown that human sparganosis can be acquired from this source. All the spargana are morphologically indistinguishable. Since these worms cannot mature in humans, they migrate into the tissues and remain as plerocercoid larvae. However, in the few instances in which the larvae were allowed to complete their life cycle in dogs or cats, they were identified as members of the genus *Spirometra*. In some cases in the United States, they were identified as *Spirometra mansoni*. Molecular approaches have been applied to this parasite that may aid in the diagnosis of this infection.<sup>60</sup>

## EPIDEMIOLOGY

Sparganosis is reported in many areas of the world, including China, Japan, Southeast Asia, and South and Central America, and has occasionally been reported in various areas of the United States and Europe.<sup>61,62</sup>

## DISEASE

The presence of plerocercoids in subcutaneous tissues is typically associated with a nodular mass consisting of tissue necrosis and a granulomatous inflammation with lymphocytes, plasma cells, and eosinophils (Fig. 115-17).<sup>63–65</sup> Swelling and edema are often painful (Fig. 115-18). Any part of the body may be involved, including the neck, breast, scrotum, and pleura.<sup>64,66–70</sup> Raw amphibian poultices harboring plerocercoid larvae applied to the eye have also been a cause of ocular sparganosis and may impair vision.<sup>71,72</sup>

Cerebral sparganosis is a rare complication of this infection. In the brain, the presence of the parasite evokes an intense inflammatory response (Fig. 115-19). Pathological and

**FIGURE 115-17** Sparganum: Abscess in muscle. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

**FIGURE 115-18** Sparganosis: Computed tomography scan of the thigh showing a circular hyperlucent lesion with inflammatory response of adjacent tissues. (From Zaiman H [ed]: Pictorial Presentation of Parasites. Audiovisual. Valley City, ND, Mercy Hospital, 1900–1982.)

radiographic (computed tomography and magnetic resonance imaging) studies demonstrate white matter degeneration, cortical atrophy, ventricular dilatation, punctuate calcifications, irregular or nodular enhancement, vasculitis, and hemorrhage.<sup>73–81</sup>

An unusual manifestation of sparganosis is a condition known as sparganum proliferum, in which larvae of a pseudophyllidean tapeworm of unknown genus and species proliferate in the tissues as independent organisms. In several instances, thousands of spargana have been found in the subcutaneous tissues.<sup>58</sup>

## DIAGNOSIS

In general, the diagnosis is based on pathological examination of biopsy or autopsy specimens and/or direct visualization of the parasite (see Fig. 115-19). In the case of

**FIGURE 115-19** Sparganum removed from the right occipital cortex. (From Kim DG, Paek SH, Chang KH, et al: Cerebral sparganosis: Clinical manifestations, treatment, and outcome. J Neurosurg 85:1066–1071, 1996, with permission of the Journal of Neurosurgery and the authors.)

cerebral sparganosis, magnetic resonance imaging is most helpful in the diagnosis and is usually followed by stereotactic biopsies.<sup>77,80</sup> Serodiagnosis using monoclonal antibodies in a competition enzyme-linked immunosorbent assay (ELISA) has been reported.<sup>82,83</sup> False-positive results may occur when *Clonorchis* and *Paragonimus* infections are present.

## TREATMENT AND PREVENTION

Treatment of sparganosis has been surgical removal of the larvae. Ocular sparganosis is sometimes treated by killing the larvae and allowing the organisms to resorb, although surgical removal has come into favor. Mebendazole, albendazole, and praziquantel have not been demonstrated to be useful. Spargana are destroyed by flash freezing at  $-10^{\circ}\text{C}$  for 24 hours.<sup>59</sup>

# Schistosomiasis

CHARLES H. KING

## INTRODUCTION

Schistosomiasis remains one of the most prevalent helminthic infections in the world. It is found in tropical and subtropical areas of South America, Africa, the Middle East, East Asia, and the Philippines.<sup>1,2</sup> Recent World Health Organization (WHO) estimates indicate that more than 200 million people are infected worldwide, with over 600 million people at risk of infection.<sup>1,2</sup> Schistosomiasis is associated with renal and bladder dysfunction (*Schistosoma haematobium*) or liver and intestinal disease (*Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, and *Schistosoma intercalatum*) in endemic areas, and it also is a contributing cause of anemia and growth retardation.

Schistosomiasis is acquired through the skin while wading or bathing in freshwater when the human host comes into contact with the infectious, free-living, cercarial larvae that are released by the parasite's intermediate hosts—aquatic or amphibious snails.<sup>2</sup> Patterns of water supply, sanitation, and human water use are, therefore, critical factors in determining the risk of infection.<sup>3</sup> In addition, the geographic distribution of the different *Schistosoma* species is entirely dependent on the distribution of the distinct snail species that serve as intermediate hosts. Climate, water quality, and other ecologic factors that regulate these snail populations also determine the distribution of schistosomiasis on a district as well as national level.<sup>3</sup>

Readily available animal models of schistosome infection have allowed intensive study of the immunology and molecular biology of schistosomiasis. Detailed analysis of host responses to these complex multicellular parasites has provided significant insight into the regulation of cell-mediated and humoral immunity,<sup>4</sup> as well as the resistance pathways available for elimination of macroparasites.<sup>5</sup> Molecular studies of the parasite<sup>6</sup> have provided information on novel modes of genetic expression, as well as leads for the development of vaccines<sup>7</sup> and new pharmaceuticals for control of this widespread chronic infection.

## AGENT

Schistosomiasis is an ancient human disease. Parasites and their eggs have been identified in early Egyptian mummies and the symptoms described in early papyrus records. In modern times, the parasite cause of schistosomiasis was identified by Theodor Bilharz in 1852 and later by Patrick Manson.

Five species of schistosomes infect humans. The three major species are *S. haematobium*, found in Africa and the Middle East; *S. mansoni*, found in Africa, the Middle East, the Caribbean, and South America; and *S. japonicum*, found in China, Southeast Asia, and the Philippines. Human infection also occurs with *S. intercalatum*, which is found in central and West Africa, and *S. mekongi*, which is found only in the Mekong river basin of Southeast Asia.

Species differences are distinguished by differences in morphology, both in the parasite stages and in their eggs. The characteristic feature of the *S. mansoni* egg is its lateral spine; of the *S. haematobium* egg, its terminal spine; and of the *S. japonicum* egg, its limited, inconspicuous spine.<sup>2</sup> Further species distinction is made by the species of intermediate host snails found to be supporting transmission of the parasite. These are *Biomphalaria* species snails for *S. mansoni*, *Bulinus* species snails for *S. haematobium*, and *Oncomelania* species snails for *S. japonicum*.<sup>3</sup>

Given the geographic differences reported in local susceptibility to antiparasitic drugs, there undoubtedly are *Schistosoma* subspecies, as well as intraspecies strain differences that exist between continents and within individual countries.<sup>8,9</sup> Recent epidemiologic studies in Kenya have focused on significant differences in the pathogenicity of *S. mansoni* infection in different areas of the country.<sup>8</sup> Clinical evidence had suggested that there might be distinct strains of *S. mansoni*, centered in discrete geographic areas, that result in significantly different levels of morbidity when local human populations are infected. Molecular biologic studies are underway confirming the genetic similarities and differences between geographic strains of *S. mansoni* in Brazil and other endemic areas.<sup>10</sup> Significant differences have also been reported between the clinical aspects of *S. japonicum* infection in China and *S. japonicum* infection in the Philippines. Recent completion of the *S. mansoni* and *S. japonicum* genome projects will shed further light.<sup>11,12</sup>

## EPIDEMIOLOGY

In endemic areas, schistosome infection is acquired in childhood. Infection increases in prevalence and intensity with age, peaking in the age group of 15 to 20 years. In older people, a drastic decline in intensity, but not in prevalence, has been demonstrated.<sup>13–15</sup> The debate is still active over whether the decline represents acquired immunity, a change in water contact, a change in egg production by adult worms, or a combination of these factors.<sup>16</sup> Schistosome infections in the human populations of endemic areas follow an overdispersed pattern, in which most infected persons show low egg counts, and a small percentage (1% to 5%) harbor extremely heavy infection. Susceptibility to high-intensity infection may reflect water exposure patterns or may be related to certain human genetic characteristics.<sup>17</sup> The epidemiology of schistosomiasis is further regulated by the duration of the parasite life span (3 to 7 years) and the multiple immunologic and non-immunologic responses of the host that participate in regulating infection and disease.

## SCHISTOSOMA MANSONI, HEMATOBIMUM AND JAPONICUM

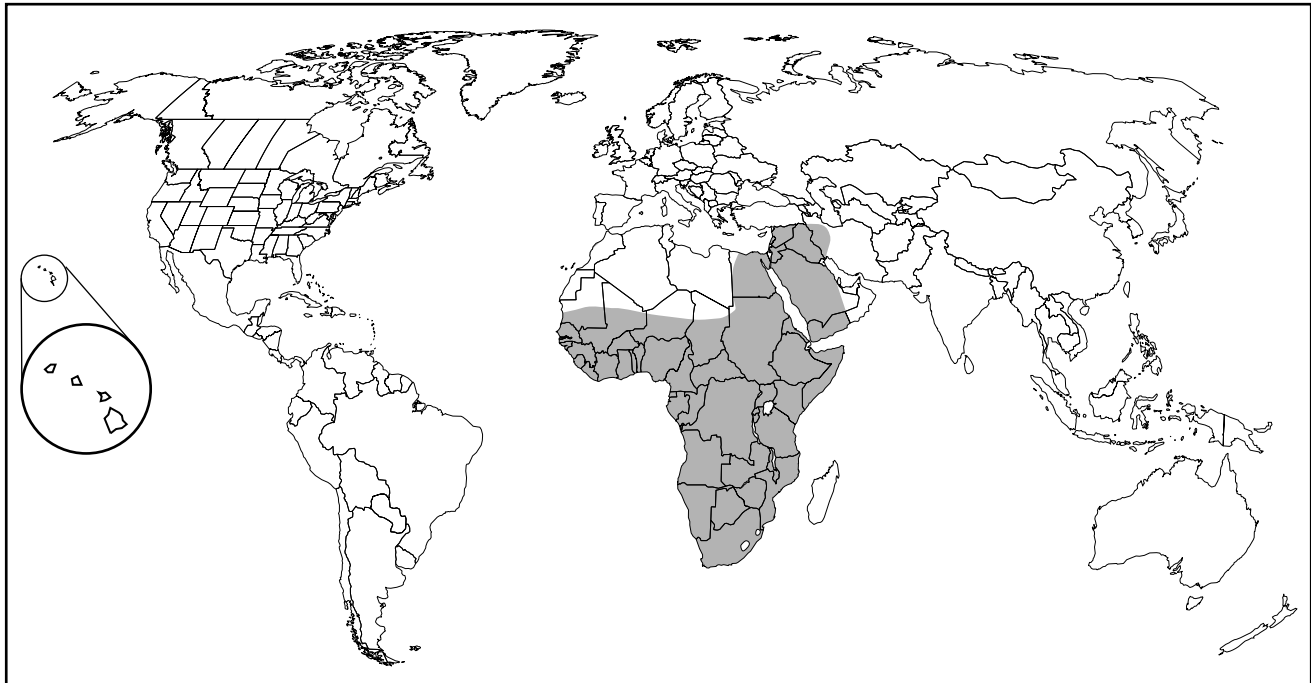

Expression of disease due to schistosome infection is similarly complex. Although adult schistosomes do not replicate in the mammalian host, they produce eggs throughout their life span. These parasite eggs elicit host immunopathologic reactions, which are responsible for most disease manifestations.<sup>18</sup> Pathogenesis may be related, therefore, to intensity of infection and certainly to factors that regulate host response, including genetic influences.<sup>19</sup>

Mathematical modeling that describes schistosome prevalence, intensity, and transmission patterns has been developed.<sup>20,21</sup> Central to these studies is the concept of quantification of infection, which is possible in helminthic infections because adult worms do not replicate in mammalian hosts. Access to quantitative data on schistosomiasis is mainly based on egg counts in feces or urine. Despite these limitations, however, useful mathematical models have been

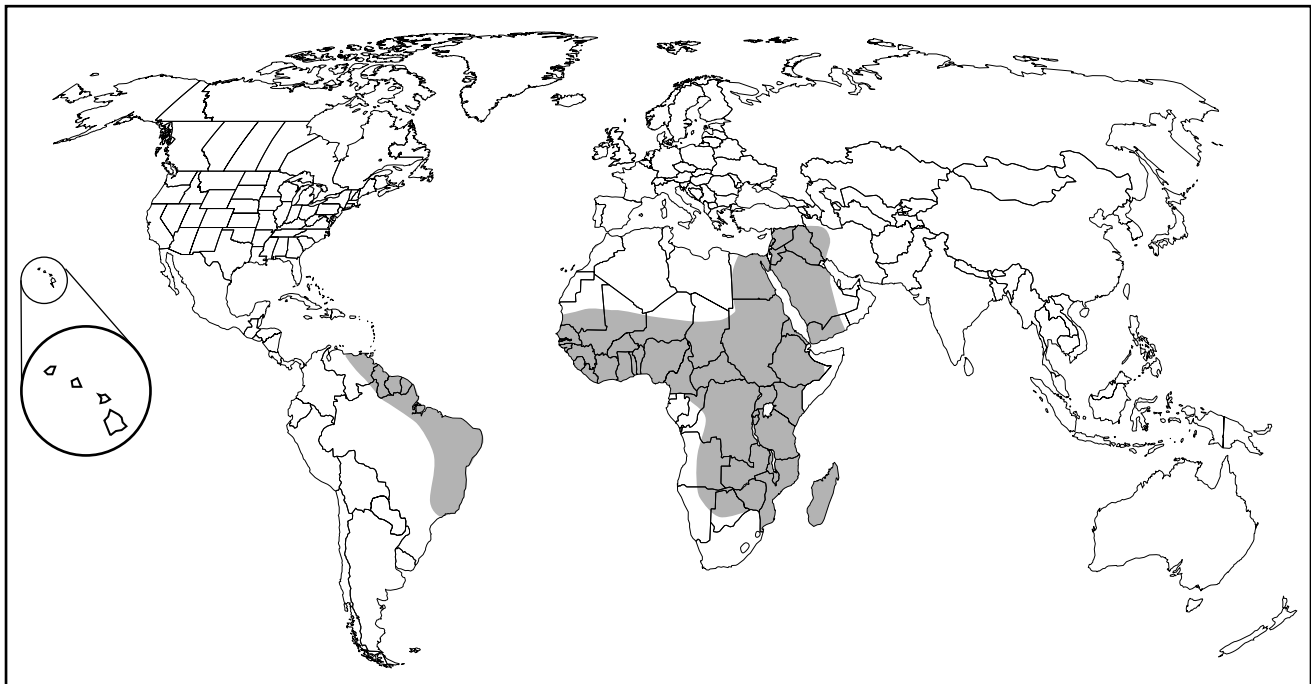

constructed for infection, its transmission, and its disease sequelae.<sup>21</sup>

## DISEASE

Illness due to *Schistosoma* infection differs between the early, or acute, stages of infection and the later disease caused by chronic infection.<sup>22</sup> Early manifestations include dermatitis and acute schistosomiasis (Katayama or "snail" fever). These are caused by initial entry of the parasite's cercarial forms into the skin, which causes a localized dermatitis, then subsequent migration of the developing schistosomulum through the lung and hepatic circulation during its development into a mature schistosome worm. The chronic disease of schistosomiasis, which is much more prevalent in endemic areas, is due to a granulomatous response to parasite eggs, resulting in

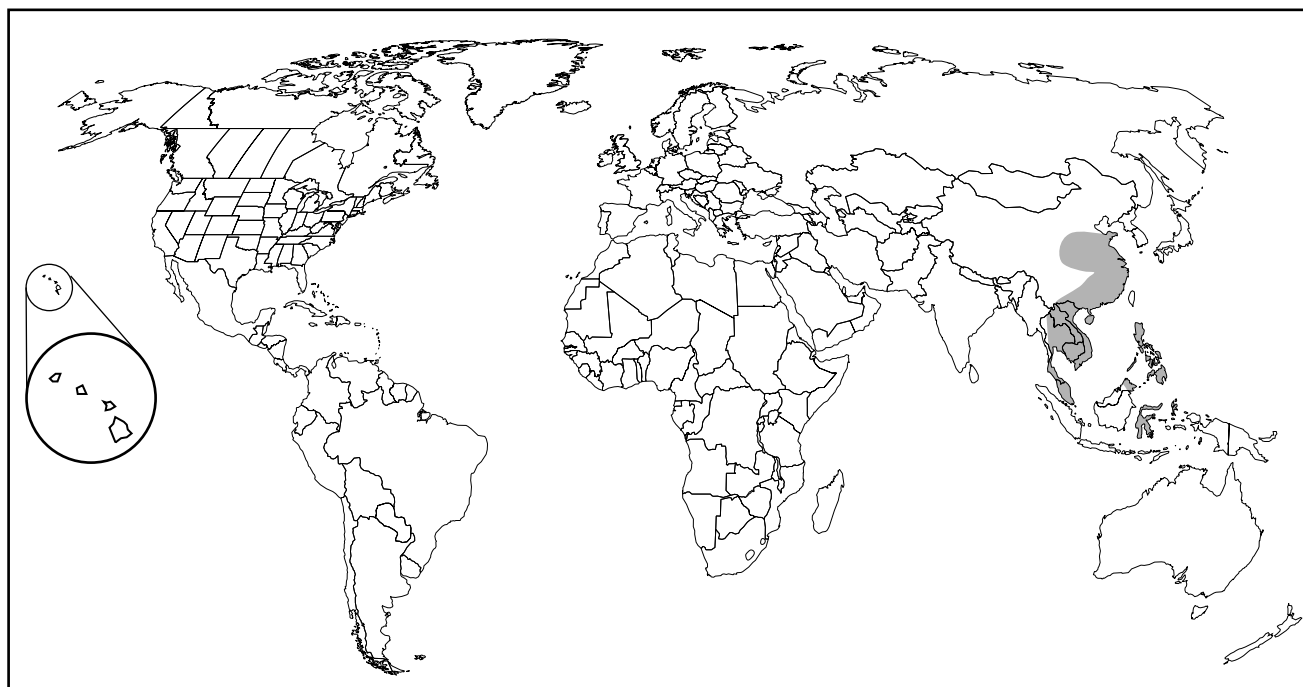

*Schistosoma haematobium*

*Schistosoma mansoni*

*Schistosoma japonicum*

chronic fibro-obstructive sequelae in the intestine or portal veins (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) or the urinary tract (*S. haematobium*).<sup>22</sup>

*Cercarial dermatitis* is a pruritic, papular rash found on skin exposed to cercaria-containing waters. In northern climates, cercarial dermatitis is the cause of “swimmer’s itch,” an eruption that occurs after abortive skin penetration by cercariae of bird schistosomes (*Trichobilharzia* and *Bilharziella*). In areas endemic for human schistosomiasis, cercarial dermatitis is most common in *S. mansoni* and *S. haematobium* transmission areas. It occurs within 24 hours after exposure, appearing as pruritic red papules on the surface of the skin. Because exposure typically occurs by walking or wading in infected ponds or rivers, the rash is usually located on the lower legs. The duration of symptoms depends on the intensity of the local cutaneous inflammatory response.

*Acute schistosomiasis* develops in some persons with heavy exposure to *S. japonicum* or *S. mansoni* infection. It is rarely seen in *S. haematobium* infection. Originally described in the Katayama Valley of southern Japan, acute schistosomiasis is most likely to occur in the traveler or new immigrant to an endemic area.<sup>23</sup> While symptoms usually resolve over several weeks, intense infection may result in death. Symptoms develop between 4 and 8 weeks after exposure, coinciding with the maturation of the infecting schistosome and the beginning of oviposition. Symptoms include fever, sweats, chills, cough, and headaches. Physical findings include lymphadenopathy and hepatosplenomegaly, and there is associated eosinophilia on laboratory examination. Early in the course of acute schistosomiasis, when egg production is just beginning, routine parasitologic diagnosis may be falsely negative due to the limited number of eggs in the stool. Biopsy or serologic testing may be required to establish the diagnosis. In fatal cases, large

numbers of eggs are found in the liver and intestines, and massive infection is the rule.

*Chronic schistosomiasis*, as seen in endemic areas, is a less dramatic, progressive illness resulting from repeated prolonged tissue injury and fibrosis from deposition of parasite eggs in affected organs: the intestine and liver for *S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*, and the bladder, ureters, and kidneys for *S. haematobium*.<sup>2</sup>

The patient with intestinal schistosomiasis may complain of fatigue, abdominal pain, diarrhea, or dysenteric bloody diarrhea caused by granuloma and ulcer formation in the bowel wall.<sup>24</sup> Granulomatous inflammation may result in polyp formation, which can be detected on barium contrast studies or endoscopy. Ulceration and chronic bleeding may lead to the development of moderate or severe iron deficiency anemia.<sup>25</sup>

In *S. mansoni*, *S. mekongi*, and *S. japonicum* infections, a significant number of parasite eggs are retained in the body and travel to the liver via the portal circulation. These eggs lodge in presinusoidal radicles of the portal vein, where they elicit a granulomatous reaction.<sup>16</sup> Venous flow is affected, first by the presence of the living egg and the surrounding granuloma formation, and later by local scar formation resulting from fibrosis. The net result is portal vein hypertension and the development of portosystemic collateral blood flow. The earliest sign of chronic schistosomiasis is hepatomegaly. As infection progresses, and liver damage becomes more severe, splenomegaly is also seen.<sup>13,26</sup> Portal pressures are markedly elevated, whereas the wedge hepatic pressure remains normal. Liver perfusion is maintained by an increase in arterial flow from the hepatic arteries. Consequently, hepatocellular function remains intact until late in the course of infection, unless alcoholism or coinfection with hepatitis B or C virus also is present.<sup>2</sup>

The major manifestations of *S. haematobium* infection are seen in children and young adults living in endemic areas.<sup>14</sup> Deposition of schistosome eggs around the lower end of ureters and in the wall of the urinary bladder results in hematuria, dysuria, and urinary frequency. In contrast to the species causing intestinal schistosomiasis, the symptoms and signs of *S. haematobium* infection are seen in a considerable percentage of those infected. The functional consequence of *S. haematobium* infection is bladder neck obstruction with back pressure causing hydroureter and hydronephrosis. Urinary schistosomiasis usually creates a setting for repeated bacterial infection, compromised kidney function, and finally renal failure.<sup>27</sup> In several endemic areas, *S. haematobium* infection is epidemiologically associated with squamous cell bladder carcinoma.<sup>28,29</sup> The relationship is such that the International Agency for Research on Cancer has classified *S. haematobium* as a human carcinogen.<sup>30</sup> While the sequence of events in *S. haematobium*-related disease seems clear, the natural history and outcome are poorly understood because of the lack of longitudinal long-term population-based studies.

Other clinical manifestations of intestinal and urinary schistosomiasis constitute important aspects of infection and disease. Among the most significant are pulmonary, central nervous system (CNS), renal, and cutaneous manifestations.<sup>31–33</sup> Pulmonary schistosomiasis results from parasite egg deposition in the pulmonary vasculature followed by granuloma formation and obstruction of blood flow.<sup>31</sup> The pathophysiologic consequence is pulmonary hypertension and the features of cor pulmonale. This course of events may occur during *S. haematobium* infection (because of the anatomic location of the adult worm) or during chronic intestinal schistosomiasis when eggs may pass to the pulmonary circulation via portosystemic collaterals.

CNS schistosomiasis causes grand mal epilepsy in 1% to 2% of persons with *S. japonicum* infection. Transverse myelitis is the usual disease entity detected in those with *S. mansoni* or *S. haematobium* infection. Disease usually occurs in chronically infected persons but may happen during the acute phase.<sup>32</sup>

## **PATHOGENESIS AND IMMUNITY**

Schistosome infection presents the host with a complex challenge. Adult worms do not replicate in the host but produce hundreds of eggs over a life span of 4 to 7 years. Eggs retained in the host tissue survive for up to 6 weeks. Host reactions are therefore complicated by these overlapping parasite factors, which result in a myriad of immunologic and nonimmunologic responses.<sup>16,24</sup> Central to the cause of disease is the cell-mediated granuloma formation and multiple humoral and cellular regulatory circuitry.<sup>16</sup> Resistance to infection with any schistosome species is both innate and acquired.<sup>7,34</sup> The role of each in regulating parasite populations is still being examined. Population-based studies suggest strongly that acquired immunity exists in humans.<sup>20</sup> The challenge is to examine such a phenomenon to understand its mechanisms and ultimately succeed in inducing resistance.

## **DIAGNOSIS**

The “gold standard” for identifying an established schistosome infection is to demonstrate parasite eggs in the patient’s

stool (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) or urine (*S. haematobium*).<sup>35</sup> Sensitivity of detection is improved by concentration and clarification techniques. Intensity of infection can be determined by quantitative sampling of defined quantities of stool (Kato template technique) or urine (syringe filtration). It should be noted that parasite eggs are deposited in the wall of the bowel or bladder and may pass into the lumen only some time later. The presence of a patent, active infection is associated with viable eggs (as determined by miracidial hatching when the eggs are placed in freshwater), whereas remote or treated infection is associated with passage of only nonviable eggs. In very heavy infections, the anatomical distribution of eggs may not be typical—that is, *S. haematobium* eggs may be found in the stool, and *S. mansoni* eggs may be found in the urine.

Infection is also defined when parasite eggs are identified in tissues obtained on rectal, intestinal, liver, prostatic, or bladder biopsy. Unfortunately, standard fixation and staining may not be able to distinguish the viability of these eggs, and it may not be certain whether the infection is current or remote. In ectopic infections (e.g., skin or CNS), or very light infections, the biopsy may be the first clue to the presence of schistosome infection.

Serologic tests have been developed to detect the presence of specific antischistosome antibodies in patients suspected of infection. Species-specific antigens have been identified on Western blotting, allowing some confidence in the determination of the infecting parasite.<sup>36</sup> However, a positive serology does not distinguish between current and past infection. In endemic populations, serology is sensitive but not specific for active infection and is therefore most useful for its negative predictive value—that is, negative serology is useful in excluding infection.<sup>2</sup> However, among travelers from nonendemic areas who have only a recent, brief, defined exposure to the parasite, and most often a low intensity of infection, positive serology strongly suggests an active infection, even in the presence of negative stool and urine parasitologic examinations.

A valuable approach to disease quantification in endemic areas has been ultrasound imaging by means of portable, generator-powered machines.<sup>37</sup> For *S. mansoni* and *S. japonicum* infection, imaging of the liver allows identification of characteristic periportal fibrosis and defines the level of disease associated with parasite infection. In *S. haematobium* infection, ultrasound examination of the kidneys and bladder allows identification of granulomas, hydronephrosis, and other inflammatory changes strongly associated with this parasite.

Recent studies have focused on alternative means of identifying active parasite infection. Workers in the Netherlands have identified two parasite antigens (CCA and CAA) that circulate in the blood during the course of active, patent infection in experimental animal models.<sup>36</sup> In subsequent studies in human populations, the level of circulating antigen was roughly correlated with the intensity of infection, suggesting that antigen detection may be a useful means of identifying and quantifying active infection. To improve participation in antigen testing, research is progressing on the use of dot-ELISA (enzyme-linked immunosorbent assay) techniques, which can be performed using a single drop of blood obtained by the fingerstick method. Studies are also progressing on antigen detection in urine, particularly for patients infected with *S. haematobium*.<sup>38</sup>

Important operational research is in progress on the use of observed macro- or microhematuria or even symptom questionnaires as surrogates for the diagnosis of *S. haematobium* infection.<sup>39</sup> Prior experience has identified the labor and material costs of parasitologic screening as significant factors in raising the cost of control programs for this parasite. Further, incomplete compliance with screening limits the participation of a significant proportion of infected persons with the later treatment phase of a control program. Studies in *S. haematobium*-endemic areas have identified that close to 100% of subjects under age 12 years with gross or microscopic hematuria are infected with the parasite. Treatment strategies based on urine dipstick diagnosis of hematuria are being validated in follow-up studies, with expected implementation in other heavily infected endemic areas.

## TREATMENT AND PROGNOSIS

Praziquantel is currently the treatment of choice for all forms of schistosomiasis.<sup>40</sup> Praziquantel is a well-tolerated, broad-spectrum oral anthelmintic agent that is given as a single dose of 40 mg/kg for treatment of *S. haematobium*, *S. mansoni*, and *S. intercalatum* infections, and as two separate 30 mg/kg doses (spaced at least 3 hours apart) for *S. japonicum* and *S. mekongi* infections. Cure rates in field studies have typically been equal to or greater than 85%. Those with infection still remaining typically have their infection intensity reduced by more than 99%, as measured by reduction in parasite egg counts in stool or urine samples. Some side effects are directly drug-induced (vomiting, dysphoria, abdominal pain), while others are proportionate to the intensity of the parasite load and appear to be related to the host immune response to the dying parasites (abdominal pain, urticaria, diarrhea).<sup>41</sup> Among younger patients, completion of therapy is associated with reductions in egg output, as well as reduced blood loss (gastrointestinal with *S. mansoni* and urinary with *S. haematobium* infection),<sup>42</sup> and regression of granulomatous inflammation in the liver (*S. mansoni* and *S. japonicum* infection) or bladder (*S. haematobium* infection). These latter effects can result in reduction of portal pressure and reversal of hydronephrosis. In older people with more advanced fibrotic tissue injury, *Schistosoma*-associated lesions may not be able to be reversed. Likewise, in patients with the late findings of esophageal varices or cor pulmonale, therapy may or may not improve their hemodynamic values. Symptomatic “ectopic” infection, as in the CNS, may initially worsen with therapy because it provokes a strong local inflammatory response. Coinfection with human immunodeficiency virus (HIV)-1 does not alter the efficacy of praziquantel therapy for schistosomiasis.

A World Health Organization (WHO) expert panel has recently reexamined the issue of praziquantel safety during pregnancy and lactation and has determined that minimal risk is associated with treatment.<sup>43</sup> WHO's recommendations are that women of child-bearing years should *not* be routinely excluded from mass treatment campaigns, and further, given the potential risks of infection-associated anemia during pregnancy, that schistosome-infected pregnant women and lactating women should be offered immediate treatment whenever the infection is diagnosed.

Several, sometimes less expensive, second-line drugs are in use for treatment of specific schistosome species.

Metrifonate is an older agent for treatment of *S. haematobium* infection. It is given as a single oral dose of 10 mg/kg. Metrifonate efficacy for parasitologic cure varies from 60% to 80%. Repeated use in the same area may be associated with decreased efficacy over time.<sup>44</sup> Oxamniquine is a second-line drug used for treatment of *S. mansoni* infection. Given in doses of 40 to 60 mg/kg as a single oral dose, it has a reported efficacy of approximately 80% in achieving parasitologic cure in most areas. *S. mansoni* resistance to oxamniquine has been documented in both Brazil and Kenya. There are currently no second-line drugs for *S. japonicum* infection.<sup>2</sup>

## PREVENTION AND CONTROL

Given the complex nature of the *Schistosoma* life cycle, there are, in theory, a number of different ways to prevent transmission of infection or reduce the likelihood of heavy infection.<sup>1,3</sup> These include (1) reduction or elimination of intermediate host snails; (2) elimination of snail habitats; (3) sanitation measures to prevent human excreta from contaminating local water sources; (4) provision of safe freshwater supplies to reduce contact with snail-infested water sources (this may include provision of communal baths, laundries, and swimming facilities)<sup>45</sup>; (5) use of protective footwear or clothing, or use of protective medicated salves to prevent cercariae from reaching the skin; and (6) use of periodic drugs to limit infection intensity in exposed populations.<sup>21,27</sup> If applied on a population-wide or targeted subpopulation basis to achieve coverage of the most heavy excretors of eggs, this last approach also results in a significant reduction in parasite transmission as a result of a substantial reduction in parasite eggs reaching transmission sites.

Each of these approaches has been tested under field conditions. Long-term eradication of schistosome transmission has been achieved in Japan and Venezuela, where water improvements and sanitation measures associated with development have eliminated transmission of *S. japonicum* and *S. mansoni*, respectively. Similarly, water supply projects, including provision of communal swimming pools, were associated with a significant reduction in *S. haematobium* prevalence in southern Iraq before the onset of the first Persian Gulf War. A head-to-head comparison of snail vector control, drug therapy, and water and sanitation measures for control of *S. mansoni* was performed over a 10-year period on the island of Saint Lucia in the Caribbean.<sup>45</sup> Although all modalities were effective in reducing infection, drug therapy was the most effective and least expensive, while provision of piped water was nearly as effective but much more expensive, requiring provision of individual household taps, as well as communal baths and laundries, to achieve comparable levels of control.

At present, the most practical approaches to control appear to be, in the short term, provision of periodic drugs to limit intensity of infection and morbidity,<sup>46</sup> and in the long term, provision of safe water supplies,<sup>47</sup> with continuing integrated health-care education<sup>48</sup> to limit high-risk exposure. Repeated drug therapy reduced the prevalence of severe morbidity in longitudinal studies. However, in some cases, particularly with *S. japonicum*, suspension of control measures runs the risk of rapid reemergence of infection prevalence and increased risk of hepatic morbidity.<sup>49</sup> Sustainability is an essential feature of any planned schistosomiasis control program. This may be difficult to achieve without assistance from developed

nations owing to the relatively high per capita cost of medication and sometimes the low priority assigned to control of a disease perceived as minimally lethal. Nevertheless, schistosomiasis has a significant impact on chronic morbidity, including malnutrition, anemia, retardation of growth and development, loss of exercise or work capacity, and either urinary tract or intestinal and hepatic disease.<sup>50</sup> Recent social science and health-care delivery research is focusing on developing more effective ways to raise awareness of schistosomiasis as a significant health problem and on developing means to incorporate schistosomiasis control into primary health-care delivery.

# Liver, Lung, and Intestinal Fluke Infections

J. DICK MACLEAN  
JOHN CROSS  
SIDDHARTHA MAHANTY

## INTRODUCTION

The trematodes that infect liver, lung, and intestine are all food-borne. Freshwater fish, crustaceans, and aquatic vegetation are the sources of human infection. Fluke diseases also are all zoonoses with reservoirs in a wide range of domestic and wild animals. It is estimated that more than 40 million people are infected with flukes, approximately 21 million with lung flukes, 20 million with liver flukes, and unknown millions with intestinal flukes.<sup>1</sup> The geographic distribution is worldwide, but the highest prevalences are in East and Southeast Asia. Distribution is determined as much by local eating habits as by the presence of the obligatory freshwater snail, crustacean, fish, or edible aquatic plant intermediate hosts. Any of these flukes can produce serious clinical disease, especially when infections are heavy. The site of preference of adult flukes for liver, lung, and intestine; the migration of the fluke larvae to these sites; the intensity of infection; and the longevity of the parasite are the major determinants of clinical disease. A most remarkable clinical feature of food-borne trematodes is the causal association between liver fluke infection and cholangiocarcinoma of the liver.

These flukes are hermaphroditic, bilaterally symmetrical, and flattened dorsoventrally with an anterior oral and a ventral sucker. Different species measure from 1 mm to 12 cm in length and have been described as spatulate, piriform, lanceolate, or leaflike in shape (Fig. 117-1).

Life cycles of the different fluke species have common features. Adult flukes in the mammalian host produce eggs that, when passed in feces or sputum, are ingested by, or hatch as, ciliated miracidia and penetrate appropriate first-intermediate-host snails, within which asexual multiplication through sporocyst, redia, and cercaria stages occurs. Free-swimming cercaria leave the snail and penetrate fish or shellfish or attach to aquatic vegetation to encyst as metacercaria. When eaten by the mammalian final host, the metacercaria excyst, migrate to liver or lungs, or stay in the small intestine and develop into adults.

## LIVER FLUKES

Human liver flukes are members of two families, the Opisthorchiidae and the Fasciolidae, distinguished by differences in life cycle and pathogenesis. In human Opisthorchiidae there are three major species (*Clonorchis sinensis* in East Asia, *Opisthorchis viverrini* in Southeast Asia, and *Opisthorchis felineus* in countries of the former Soviet Union) and two minor species (*Opisthorchis guayaquilensis* in North and South America and *Metorchis conjunctus* in North America). In the Fasciolidae the species are *Fasciola hepatica*, which has a worldwide distribution, and *Fasciola gigantica* in South Asia, Southeast Asia, and Africa.

## OPISTHORCHIASIS AND CLONORCHIASIS

### AGENTS

The three major Opisthorchiidae species—*C. sinensis*, *O. viverrini*, and *O. felineus*—have similar life cycles and pathogenic processes. Differentiation among species is usually based on adult fluke morphology or geographic distribution, as differences in egg morphologies are small.<sup>2,3</sup> Adults, which live in the intrahepatic bile ducts of their host, are flat, spatulate to lanceolate, aspinous, and reddish to brown in color. *C. sinensis* is the largest (10 to 25 mm × 3 to 5 mm), in contrast to the smaller *O. viverrini* (5 to 10 mm × 1 to 2 mm) and *O. felineus* (7 to 12 mm × 2 to 3 mm; Fig. 117-2A). The adults produce ovoid eggs that are yellowish-brown, have opercula, and are of such overlapping and variable size (*O. viverrini*, 30 μm × 12 μm; *O. felineus*, 30 μm × 12 μm; *C. sinensis* 28 to 35 μm × 12 to 19 μm) that speciation is very difficult (Fig. 117-2B).

The eggs, if deposited in fresh water and ingested by the appropriate snail, hatch as miracidia and metamorphose into sporocysts and then redia. These then transform into free-swimming cercaria on leaving the snail and penetrate and then encyst as metacercaria in susceptible freshwater fish species. These metacercaria, in uncooked fish, are ingested by the final human host, excyst in the duodenum, mature rapidly into adults, and migrate through the sphincter of Oddi and up the common bile duct to become wedged in the intrahepatic biliary radicles. The prepatent period is 3 to 4 weeks, and the life span in the human host can be as long as 30 years.

### EPIDEMIOLOGY

*C. sinensis* is endemic in China, Japan, Korea, Taiwan, Vietnam, and Asian Russia. In China, infection is endemic in 24 provinces, with prevalence rates between 1% and 57%; the greatest number of cases is in the southeastern province of Guangdong and the southern region of Guangxi Zhuangzu.<sup>4</sup> Hong Kong is not an endemic area for the parasite; infections are acquired by eating fish imported from the mainland of China. In Korea rates of 8% to 22% were reported in the past, while prevalence rates in the 1990s dropped to 2%. People living along river basins are more commonly infected. This parasitosis is reported from all areas of Taiwan, with the highest infection rates of 52% to 57% from three widely separated

**FIGURE 117-1** Threefold magnification of selected flukes illustrating relative sizes. Actual lengths: *Metagonimus yokogawai* 1.0 to 2.5 mm, *Nanophyetus salmincola* 0.8 to 2.5 mm, *Metorchis conjunctus* 1.5 to 7.0 mm, *Opisthorchis viverrini* 5 to 10 mm, *Paragonimus westermani* 7 to 16 mm, *Clonorchis sinensis* 10 to 25 mm, *Fasciola hepatica* 20 to 30 mm, *Fasciolopsis buski* 20 to 75 mm. (*Metagonimus yokogawai* image from Centers for Disease Control and Prevention, Division of Parasitic Diseases, Atlanta, GA; *Nanophyetus salmincola* and *Fasciolopsis buski* images courtesy of Steve J. Upton, Kansas State University; *Opisthorchis viverrini* image from Ash LR, Orihel TC: Atlas of Human Parasitology. Chicago, ASCP Press, 1990, plate 73, #2, p. 213; *Paragonimus westermani*, *Clonorchis sinensis*, and *Fasciola hepatica* images from Orihel TC, Ash LR: Parasites in Human Tissues. Chicago, ASCP Press, 1995, figures 72, 60, and 58, pp. 272, 268, and 264.)

areas in northern, central, and southern counties of the island.<sup>5</sup> Although clonorchiasis was found in up to 3% of the Japanese population prior to 1960, by 1991 the disease had almost disappeared. Endemic areas in Russia are in the Amur River area.

*O. viverrini* is highly endemic in the northeastern region of Thailand and Laos, where prevalence rates of more than 24% and 40% to 80%, respectively, are reported.<sup>1,6</sup> There are reports of occurrence from Vietnam with rates of 0.3% to 37%.<sup>7</sup>

*O. felinus* has been reported from an estimated 16 million people in the former USSR, with endemic foci in western Siberia, the Russian Federation, Kazakhstan, and Ukraine; prevalences range from 40% to 95%.<sup>1</sup>

Other opisthorchiids reported from humans are *Opisthorchis guayaquilensis* (*Amphimerus pseudofelineus*) and *Metorchis conjunctus*. These have been reported from animals and humans in Latin America and North America. An epidemic of metorchiasis occurred in 19 persons in Canada who had eaten freshly caught white suckers (*Catostomus commersoni*) near Montreal.<sup>8</sup>

A variety of hydrobid snails serve as first intermediate hosts for *C. sinensis*, *O. viverrini*, and *O. felinus*. *Bithynia fuchsiana*, *Parafossarulus manchouricus*, and *Simulcospica libertina* are important vectors of *C. sinensis* in most endemic areas, while *Bithynia siamensis* is a vector of *O. viverrini* in Thailand; *Melanoides tuberculatus* is an important vector in Vietnam<sup>7</sup>; and *Codiella inflata*, *Codiella troscheli*, and *Codiella leachi* are vectors of *O. felinus* in the former USSR. These snails are found in freshwater bodies and are abundant in fish-raising ponds in China, Taiwan, and Thailand.

Over 100 species of fish, many of them synonyms, are reported as second-intermediate hosts of *C. sinensis*. Most are carps of the family Cyprinidae; *Ctenopharyngodon idellus* in China, *Cyprinus carpio* in Japan, and *Pseudorasbora parva* in Korea are often eaten raw. Many of the fish are cultivated in ponds inhabited by snail hosts, and the ponds are contaminated or intentionally fertilized with human and animal feces. Fifteen species of cyprinoid fish such as *Cyclocheilichthys* spp. and *Puntius* spp. are sources of infections in Thailand, and *Carassius carassius* and seven other species are sources in Vietnam.

**FIGURE 117-2** *Clonorchis sinensis*. A, Adult (size 10 to 25 × 3 to 5 mm). B, Egg (size 29 × 16 μm). (From Orihel TC, Ash LR: Parasites in Human Tissues. Chicago, ASCP Press, 1995.)

Cultured fish, as well as fish from natural sources, are infected, and as the streams dry up, fish clustering in shallow waters are easily caught and eaten raw. Twenty-two species of cyprinids are intermediate hosts for *O. felineus* in the former USSR. The fish, such as *Barbus barbus* and *Tinca tinca*, may be eaten raw, dried, salted, and sometimes frozen.

In endemic areas of opisthorchiid liver fluke infections, a myriad of mammalian hosts such as dogs, cats, pigs, rats, rabbits, and other wild fish-eating animals serve as reservoir hosts.

## DISEASES

There is consensus that the biologic and pathologic characteristics of *Opisthorchis* and *Clonorchis* are the same. Variations in clinical presentations seen in different geographic areas are thought to reflect the duration and intensity of infection as well as the genetics and nutrition of the host rather than parasite-specific characteristics.<sup>9</sup> Acute disease has been recognized most frequently in *O. felineus* infections in Russia. The risk of cholangiocarcinoma appears greatest in *O. viverrini* infections in northern Thailand. Intrahepatic pigment stones are reported more frequently in association with *C. sinensis*.<sup>9</sup> Chronic infections are usually asymptomatic,

although symptoms may occur in heavier infections. The complications of chronic infection include acute cholangitis, frequently bacterial, and cholangiocarcinoma.

## Acute Opisthorchiasis and Clonorchiasis

Acute illness due to new infections with *C. sinensis* has rarely been reported except for a large outbreak of acute clonorchiasis in Shanghai in the 1940s.<sup>10,11</sup> The illness lasted several weeks and was characterized by persistent fever, abdominal pains, fatigue, an enlarged and tender liver, high eosinophil counts, and opisthorchiid eggs in the stool after 3 to 4 weeks.<sup>10</sup> In Russia acute opisthorchiasis has been seen frequently in migrant populations settling in regions endemic to *O. felineus*.<sup>12,13</sup> The presentation is fever, abdominal pain, and urticaria. In Canada an outbreak of acute illness due to *M. conjunctus* reported upper abdominal pain, moderate fever, anorexia, high eosinophil counts, and opisthorchiid eggs in the stool late in the second week of illness.<sup>8</sup>

## Chronic Opisthorchiasis and Clonorchiasis

Light to moderate infections, lasting for years or decades, are almost always asymptomatic.<sup>14</sup> Case-control and

# Liver Flukes

*Clonorchis sinensis*  
*Opisthorchis viverrini/felineus*\*

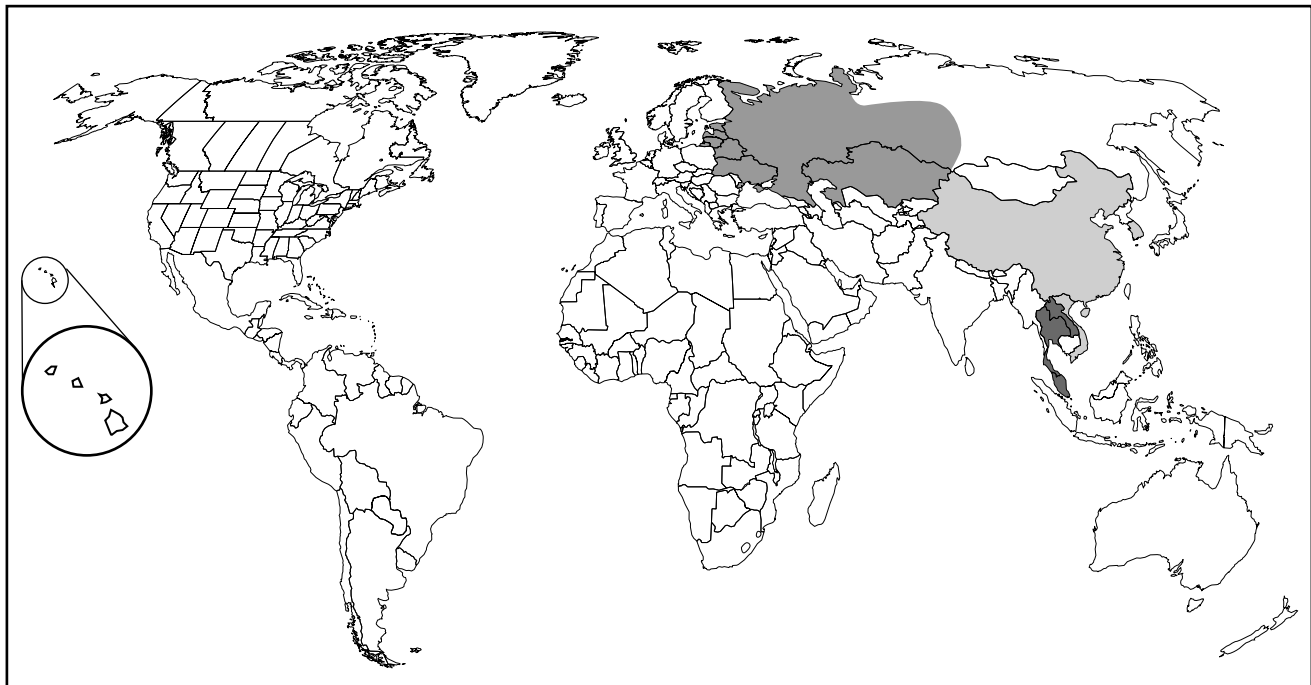

community-based studies have revealed no differences in the signs, symptoms, or laboratory findings between light infections and uninfected controls, but cases with heavy infections (more than 10,000 eggs per gram) show significantly more abdominal pain, fatigue, dyspepsia, and hepatomegaly.<sup>15-18</sup> There is a correlation between stool egg counts, adult fluke counts, and host disease in *Opisthorchis* infection. But even in heavily infected persons, abdominal symptoms occur in only 10%.<sup>9,19-23</sup> Such studies are difficult to interpret because raw fish consumption in many communities is frequent and reinfection likely.<sup>15,18,24,25</sup>

Many uncontrolled hospital-based studies in endemic regions demonstrate a variety of intermittent symptoms that increase in frequency in those with heavy infections.<sup>26,27</sup> These symptoms include intermittent fatigue, abdominal pain

and fullness, anorexia, weight loss, and diarrhea. In these studies, physical signs, such as liver enlargement and tenderness, are more frequent in the heavily infected, and eosinophil counts are higher. Uncontrolled treatment trials with praziquantel have demonstrated a decrease in symptoms of upper abdominal pain, diarrhea, distention, dizziness, fatigue, and insomnia from 72% to 45%.<sup>28</sup>

Ultrasonographic studies have revealed a high frequency of gallbladder enlargement, sludge, dysfunction, and stones in asymptomatic moderately to heavily infected patients. Treatment appears to reverse these parasite-associated gallbladder abnormalities.<sup>19,29,30</sup>

Pathologic changes observed on necropsy and biopsy relate to intensity and duration of infection. Early infections reveal bile duct proliferation and pseudostratification of the

### Opisthorchiidae

- ▨ *Clonorchis sinensis*
- *Opisthorchis felineus*
- *Opisthorchis viverrini*

biliary epithelium. Later, metaplastic squamous cells and glandular proliferation appear, suggesting adenomatous hyperplasia.<sup>31</sup> A small percentage of patients with chronic infection will develop complications, which include recurrent ascending cholangitis, pancreatitis, and cholangiocarcinoma.

### Recurrent Ascending Cholangitis and Pancreatitis

Recurrent ascending cholangitis is characterized by repeated episodes of fever, chills, jaundice, right upper quadrant pain, gram-negative sepsis, and leukocytosis. Soft, muddy pigment stones are found in the biliary radicles and common bile duct and are associated with dilated intrahepatic bile ducts, ectasia, strictures, and multiple pyogenic abscesses, most notably of the left lobe of the liver.<sup>32</sup> Recurrent exacerbations and remissions can occur over years.<sup>33,34</sup> Pancreatitis at times is found on endoscopic retrograde cholangiopancreatography (ERCP), or at the time of surgery or autopsy, but it is rarely symptomatic or found in isolation without liver involvement.<sup>35,36</sup>

### Cholangiocarcinoma

An increased frequency of cholangiocarcinoma of the liver is seen in northern Thailand, where case-control studies reveal a fivefold increased risk in those infected.<sup>37</sup> The risk increases to 15-fold in persons with heavier infections. In one endemic province of Thailand, the rate of cholangiocarcinoma

in males and females was ten- and sixfold higher, respectively, than in a nonendemic area.<sup>37,38</sup> In animal studies, nitrosamines increase the incidence of cholangiocarcinoma in *Opisthorchis*-infected animals.<sup>39–41</sup> High levels of such substances have been noted in the northern Thai diet.<sup>42</sup>

### PATHOGENESIS AND IMMUNITY

The pathologic changes seen in the liver and biliary system in clonorchiasis and opisthorchiasis are believed to be the result of mechanical injury by the suckers of the flukes and host interactions with their secreted metabolic products.<sup>43–45</sup> Dilated hyperplastic bile ducts have been associated with excess proline production by adult flukes.<sup>46</sup> The eggs probably serve as nidi for biliary stones in the bile ducts and gallbladder.<sup>31,47</sup> Immunohistochemical studies indicate that the excretory-secretory proteins from the digestive and excretory organs (i.e., the intestines and bladder) are the most potent antigens and likely induce the dominant immunologic response.<sup>4</sup> Periductal infiltration with eosinophils and round cells with fibrosis of portal areas—a common finding—suggests that immune-mediated tissue damage is involved in the pathogenesis of disease.<sup>4</sup> The local reactions to eggs and migrating parasites are driven by T-lymphocyte effector mechanisms and are regulated by the CD4+ subset of T lymphocytes.<sup>48</sup> The presence of apparently uninfected persons in endemic regions with significantly higher levels of parasite-specific IgM, IgG, and IgA than egg-excreting persons has been used as evidence of protective immunity.<sup>44,49,50</sup>

## DIAGNOSIS

Asymptomatic infections with Opisthorchiidae are diagnosed by the presence of characteristic findings on ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) or by the detection of eggs in stool. On ultrasound of the liver, the combination of cystic or mulberry-like dilations of intrahepatic bile ducts is pathognomonic of opisthorchiasis. With M-mode ultrasound, numerous spotty echoes and thin linear and moving intraductal echoes may be seen.<sup>35,51,52</sup> Examination of multiple stool specimens may be necessary in lighter infections, but in infections of less than 20 adult flukes, no eggs may be found.<sup>22</sup> While egg counts in stools are relatively stable over time and such egg counts have prognostic significance, low egg counts may be seen in the heaviest infections because of blockage of biliary radicles or because pyogenic ascending cholangitis has killed the adults.<sup>21,22,53</sup> The eggs of *Clonorchis*, *Opisthorchis*, and *Metorchis* are essentially indistinguishable from one another by routine microscopy and can be confused with other fluke eggs as well. A definitive diagnosis may be made by examining the adult flukes in the stool immediately after a praziquantel treatment and purge or at the time of surgery.<sup>20,53,54</sup>

The diagnosis of acute infection is based on a history of raw freshwater fish consumption (salted, fermented, or smoked fish, fish sauces, fish condiments), followed within several weeks by upper abdominal pain, high-grade eosinophilia, liver enzyme elevation, and the appearance of compatible eggs in the stool.

## Immunodiagnosis

Immunologic tests generally complement parasitologic testing and until recently have not had a primary role in the diagnosis of opisthorchiasis and clonorchiasis. These tests are not widely available in endemic regions and do not distinguish active infections from past exposure or cured infections.<sup>55</sup> Intradermal tests using crude extracts of adult flukes have been used for detection of infection in epidemiologic surveys and have proved very sensitive (92%), showing no cross-reactions with other nematode infections.<sup>4</sup> However, these tests remain positive for many years after exposure to the parasite. The preferred assay for immunodiagnosis is the determination of antibody levels by enzyme-linked immunosorbent assay (ELISA). When compared with egg-positive stools, sensitivity can be high (79% to 96%).<sup>4</sup> However, ELISA using crude worm extracts is handicapped by significant lack of specificity; antibody positivity is seen in cases of paragonimiasis (33%), schistosomiasis japonica (5% to 25%), cysticercosis, hepatitis, liver cancer, and tuberculosis.<sup>56,57</sup> Specificity can be enhanced somewhat by using immune affinity-purified antigens.<sup>58</sup> More recently, the use of monoclonal antibodies in an ELISA inhibition test has proved to be sensitive (77%) and more specific (virtually no cross-reactivity with other trematode infections) than the ELISA using crude worm extracts.<sup>4</sup> Approaches used to refine and improve specificity of ELISA assays have included the use of excretory-secretory (ES) antigens as plate antigens.<sup>59</sup> A number of proteins have been identified as major components of ES preparations of *C. sinensis*, including cysteine proteases and glutathione-S-transferase.<sup>60</sup> The modifications to ELISAs have been reported to achieve

sensitivities and specificities of greater than 95% in smaller serologic surveys, but their utility in large-scale surveillance is yet to be proved.<sup>61</sup> After treatment, antibody levels return to normal by 6 months in more than half of cases.<sup>4,62</sup> Circulating antigen detection with a monoclonal antibody-based capture ELISA has been found to detect as little as 30 ng/mL of *C. sinensis* antigen in serum. Antigen positivity is seen in 95% of antibody-positive infected patients. This test was reported to be positive in 95% of seropositive infected patients, declining to undetectable levels after 3 months in 81% of those parasitologically cured.<sup>63,64</sup> Stool antigen detection techniques show similar promise.<sup>65</sup>

## TREATMENT

Praziquantel has been the drug of choice for opisthorchiasis and clonorchiasis since the 1970s because of ease of administration, lack of side effects, and demonstrated effectiveness. The recommended dosage of 25 mg/kg three times daily for 2 days has produced cure rates up to 100%, but patients with heavy infections (more than 5000 eggs per gram of stool) and some geographic regions where praziquantel cure rates are low (North Vietnam) may require retreatment.<sup>4,31,66,67</sup>

Albendazole has produced cure rates of 93% to 100% at a dosage of 10 mg/kg daily for 7 days.<sup>4,68</sup> Although some studies have suggested that it may not be as effective as praziquantel, it has fewer side effects.

Treatment success is defined by the disappearance of fluke-induced symptoms and fecal egg output, reduction in liver size, and a reversal of biliary tract abnormalities.<sup>19</sup> Recurrent pyogenic cholangitis is primarily a surgical problem, requiring relief of intrahepatic obstructions due to strictures, stones, and sludge, and drainage of the associated abscesses. Antibiotics may be necessary to treat the associated sepsis, and praziquantel is used to eradicate the remaining flukes.<sup>69</sup>

## FASCIOLIASIS

Among the Fasciolidae there are two human flukes: *Fasciola hepatica*, the most common and widely distributed, and *Fasciola gigantica*, a fluke of much more focal distribution. Both have similar life cycles and produce similar human disease, but *F. gigantica* can be recognized by its larger adult and egg sizes.

## AGENTS

The adult *F. hepatica* is a large fluke (30 mm long × 15 mm wide), flat and leaflike along the margins, with a cephalic cone (Fig. 117-3A). As for other flukes, size, shape, and integumental and internal morphology are species-defining features. The adult fluke lives in the common and hepatic bile ducts of the human or animal host, and eggs reach the exterior via the sphincter of Oddi and the intestine. The eggs are large (130 to 150 μm × 60 to 90 μm), ovoid, and inconspicuously operculate (Fig. 117-3B). In water, miracidia hatch from the eggs and penetrate suitable snail hosts where, after multiplying as sporocysts and redia, they leave the snail as free-living cercaria.

**FIGURE 117-3** *Fasciola hepatica*. A, Adult (size 30 × 15 mm). B, Egg (size 130 to 150 × 60 to 90 μm). (From Orihel TC, Ash LR: Parasites in Human Tissues. Chicago, ASCP Press, 1995.)

These attach to suitable plants, evolve into metacercarial cysts, and when ingested by the human final host, excyst in the duodenum. The larvae migrate through the small intestinal wall and through the peritoneal cavity where they penetrate the liver capsule and slowly migrate to the large hepatic ducts. This prepatent period lasts 3 to 4 months. Anecdotal reports suggest that the life span in the human host can be up to 10 years.

## EPIDEMIOLOGY

*F. hepatica* has been reported from 61 countries worldwide, especially in sheep-raising areas.<sup>70</sup> More than 2 million people are infected, mostly in Bolivia, Peru, Iran, Egypt, Portugal, and France. A variety of freshwater plants upon which metacercariae encyst, such as watercress, water lettuce, mint, and parsley, are important sources of human infection because they are often eaten raw in salads.<sup>71</sup> Over 25 species of amphibious lymnaeid snails serve as the first intermediate host for *F. hepatica*. The most important is *Lymnaea truncatula*, which lives in wet mud along the shoreline, rarely in fast-moving or deep waters. The major natural reservoirs for *F. hepatica* are cattle, sheep, goats, buffalo, camels, llamas, deer, pigs, horses, rabbits, and other wild animals. It is not uncommon to find high levels of infection with *F. hepatica* or *F. gigantica* in domestic and wild ruminants of endemic areas; prevalence rates of 25% to 92% are seen in Bolivia, 20% to 40% in Ecuador, 10% to 100% in Peru, and 20% to 40% in Iran. In humans, stool- or antibody-positive prevalence rates in these countries can be similarly high (65% to 92% in Bolivia, 24% to 53% in Ecuador, 2% to 17% in Egypt, and 10% in Peru).<sup>1</sup>

## DISEASE

The clinical presentation of infection with *F. hepatica* reflects its peregrinations in the human host. Hepatic transit, variably called the hepatic, larval, invasive, or acute stage, lasts several months. This is followed by the biliary, adult, or chronic stage, which can persist for years. Where repeated ingestion of metacercariae occurs over an extended period, these two stages can overlap.<sup>72</sup>

### Acute Hepatic (Invasive) Stage

Within 6 to 12 weeks of ingestion of metacercariae, symptoms occur that reflect larval migration through the small intestinal wall, the peritoneal cavity, and liver capsule.<sup>73</sup> This acute stage can last for 2 to 4 months. One large study revealed typical findings of fairly marked eosinophilia (95%), abdominal pain (65%), intermittent fever (60%), malaise and weight loss (35%), urticaria (20%), and cough, dyspnea, and chest pain (15%). A change in bowel habits, anorexia, and nausea may occur.<sup>74,75</sup> The abdominal pain may be generalized but frequently becomes localized to the right hypochondrium.<sup>76,77</sup> Hepatomegaly is a variable finding, and the liver may be tender on palpation. In some cases, mild elevations of hepatic enzymes are noted. The pulmonary symptoms may be associated with right-sided pleural effusions, which, on aspiration, reveal increased eosinophils.<sup>78</sup> Anemia has been reported.<sup>79,80</sup>

Ultrasound examination of the liver in the acute stage is usually normal although small amounts of ascites have been found.<sup>78</sup> CT scans frequently reveal single or, more frequently, multiple small hypodense lesions 2 to 10 mm in diameter.<sup>74</sup> In addition, tunnel-like, branching, hypodense lesions (best delineated with contrast), most frequently situated peripherally

# Liver Flukes

## *Fasciola hepatica* (& *gigantica*)

in sheep (& cattle) raising areas of Europe, Africa, Asia, and N. & S. America

\* Rarely also seen ectopically in skin or bowel wall; stool exam is usually negative at this early stage

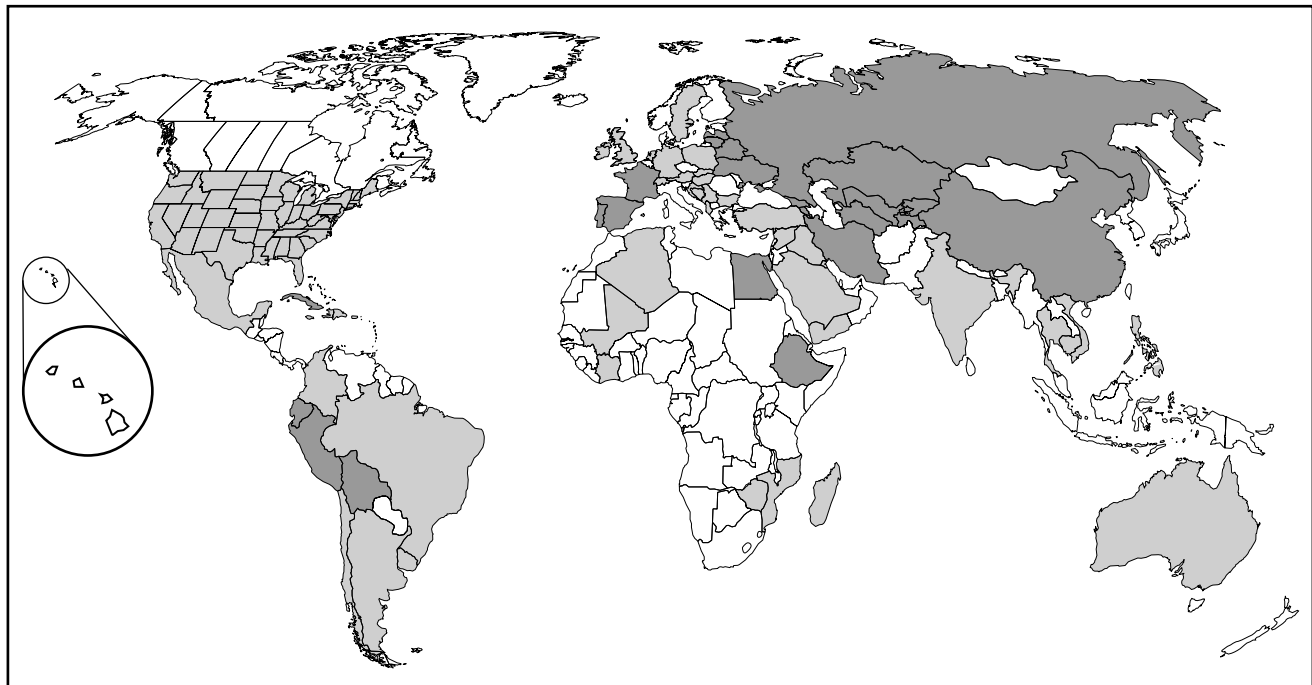

within the liver, are relatively specific for fascioliasis, representing the pathologic changes created by the migration of the immature fluke through the liver.<sup>81</sup> The hepatic lesions are remarkable in that, on sequential CT scans, the position, attenuation, and shape of the lesions change over time.<sup>82</sup> On laparoscopy, multiple gray-white and yellow nodules 2 to 20 mm in diameter and short vermiform cords are noted on the liver surface and at times on the adjacent peritoneal surface.<sup>83</sup> Liver biopsies reveal microabscesses and tunnel-like areas of parenchymal necrosis surrounded by inflammatory infiltrates containing abundant eosinophils.<sup>81,84</sup> Necropsies reveal multiple subcapsular cavities 5 to 10 mm in diameter filled with necrotic material from which necrotic tracts radiate. Increasing fibrosis is seen in older lesions.<sup>84,85</sup>

Rarely, immature flukes may migrate to nonhepatobiliary locations such as the skin, lung, intestinal wall, brain, and

genitourinary tract, where granulomatous nodules or small abscesses lead to local clinical findings. Migrating erythematous 1.5- to 6.0-cm cutaneous nodules are another form of cutaneous larva migrans.<sup>72,74,85,86</sup>

### Chronic Biliary (Obstructive) Stage

*F. hepatica* has a propensity to migrate to the lumen of the common bile duct, where it reaches maturity. Eggs appear in the stool after a prepatent period of 3 to 4 months. Clinical findings reflect this new luminal location in that the liver-destructive phase of the infection ends. Fever, anorexia, and abdominal pain resolve, and the patient may become asymptomatic. Eosinophilia is infrequent. An unknown percentage of these cases develop the complication of intermittent biliary obstruction with symptoms that can include intermittent pain

### Fasciolidae

- *Fasciola* endemic
- *Fasciola* sporadic

in the epigastrium or right hypochondrium, mimicking biliary colic or acute cholecystitis. At times the presentation is that of ascending cholangitis with fever, jaundice, and upper abdominal pain.

Ultrasound examination (more effective than CT examination at this stage) often reveals a soft intraluminal mass obstructing the extrahepatic biliary tree. Lithiasis of the common bile duct and gallbladder is a common sequela.

### PATHOGENESIS AND IMMUNITY

Morbidity from *F. hepatica* is dependent on the number of worms and stage of infection.<sup>87</sup> The characteristic hepatic (and extrahepatic) changes of fascioliasis result largely from the anatomic location and large size of the parasite, a foreign body that induces eosinophilic and mononuclear infiltration around the eggs and adult worms.<sup>43</sup> As in other tissue-invasive helminthic infections, fascioliasis is associated with prominent eosinophilia, particularly in the early stages of infection.<sup>74,87</sup> As with most helminths, immune responses to *F. hepatica* appear to be regulated by a subpopulation of T-helper cells designated as subtype 2 (Th2) cells, characterized by secretion of interleukin (IL)-4, IL-5, and IL-10.<sup>88,89</sup> This pattern of T-helper cell response also appears to regulate granuloma formation and liver disease in schistosomiasis.<sup>48,90,91</sup> However, the roles of T-cell and other non-antibody-mediated effector systems in killing of the parasite and in the development of pathologic changes are not well understood.<sup>92,93</sup> The role of eosinophils in parasite killing is also unclear, although it has been noted that the invasive phase in the liver is associated with peripheral eosinophilia and eosinophilic infiltrates around the sites of

parasites and eggs in the liver.<sup>72,84</sup> Recombinant parasite-derived molecules have been used to vaccinate the host before challenge with infective stages of the parasite.

Immune evasion mechanisms are likely to play an important role in the survival of this long-lived parasite, and several evasion strategies have been proposed.<sup>94</sup> The surface glycocalyx may mediate immune evasion in several ways. First, the glycocalyx changes in composition during development of the parasite. Second, the glycocalyx is continuously sloughed off by the maturing juvenile worm, by one estimate every 3 hours, thus presenting a moving target.<sup>95</sup> Third, glycocalyx released from the surface can mop up circulating antibodies, interfering with immune effector functions that involve them, such as antibody-dependent cellular toxicity (ADCC).<sup>96</sup> Other relevant strategies include migration away from inflammatory cells, inhibition of oxygen radical generation by macrophages and inhibition of T-cell function.<sup>97</sup> Natural resistance to fatal infection with *F. hepatica* has been observed in sheep and several strains of mice. Relative resistance to infection in mice correlates with type 1 (IFN- $\gamma$ ) responses, whereas type 2 responses are associated with susceptibility.<sup>94</sup> Protection from challenge infection in mice and rats can be transferred by passive transfer of serum, but this protective effect is limited to sera collected 7 to 8 weeks post-donor infection; after 25 weeks, serum from infected rats gave no protection, presumably owing to a decline in titers that accompanies the entry of the parasite into bile ducts.<sup>95</sup> Several potential vaccine antigens have been identified from animal models of *F. hepatica* infection. Defined antigens that are targets of antibody responses include fatty acid-binding proteins, glutathione-S-transferase (GST), cathepsin-L, and fluke hemoglobin.<sup>97-99</sup> Two molecules have

been shown to confer partial resistance to infection in experimental infections. One is a GST, and the second is a 14.7-kD polypeptide (Fh15) that has significant homology to, and cross-reacts with, *Schistosoma mansoni* fatty acid-binding protein.<sup>100–102</sup> The *F. hepatica* GST has been shown to protect sheep against experimental infection.<sup>93</sup> Overall, vaccine studies, using cocktails of recombinant antigens in animal models of fascioliasis, have shown that significant reductions in worm burdens (31% to 72%) and egg production (69% to 98%) can be achieved.<sup>93,103</sup>

## DIAGNOSIS

*F. hepatica* eggs are not found in stool specimens during the acute phase. The diagnosis must be based on the clinical findings of persistent pain and tenderness in the right hypochondrium or epigastrium, altered intestinal function, mild to moderate fever, and blood eosinophil counts in the thousands per microliter.<sup>82</sup> CT scans (ultrasound is less sensitive) contribute to the diagnosis, since the majority of symptomatic patients have visible hypodense lesions and tracts in the liver and over time these lesions change in position and contour. The differential diagnosis of this clinical and radiologic syndrome includes visceral larva migrans caused by *Toxocara canis*, which usually also shows pulmonary symptoms. Needle biopsies of the liver have not been used for diagnosis. Laparoscopy may reveal elongated nodules in the liver capsule.

In the acute invasive period, lasting 3 to 4 months, immunologic techniques are valuable diagnostic tools. Skin tests using adult worm antigens or purified fractions of *F. hepatica* were used in the 1960s and 1970s; these tests were sensitive but not very specific.<sup>104,105</sup> Other tests have been employed with varying success, including complement fixation (CF), immunofluorescent (IF) assays, indirect hemagglutination (IHA), countercurrent electrophoresis (CEP), and ELISA.<sup>72,106–111</sup> ELISAs have largely replaced other techniques because they are sensitive, rapid, and quantitative.<sup>109,111,112</sup> The preferred ELISAs employ excretory-secretory products of the adult worm as an antigen.<sup>112–114</sup> Antibodies to excretory-secretory antigens are elevated early in infection (based on studies in animal models) and remain elevated for years after infection although successful treatment correlates with a decline in ELISA titers.<sup>71,115</sup>

More recently, the Falcon assay screening test–ELISA (FAST-ELISA), a simple and rapid assay based on the ELISA and enzyme-linked immunoblot transfer assay, has been used for serodiagnosis, achieving sensitivities of 95% to 100% compared with parasitologic diagnosis.<sup>111,116</sup> However, the specificity of this test is not known and may limit its utility.<sup>74</sup>

An ELISA antigen capture technique to detect circulating antigens has demonstrated a sensitivity of 100% and specificity of 98%.<sup>117</sup> Antigen detection techniques can detect parasite antigens in stool specimens 3 to 4 weeks before the appearance of eggs.<sup>80</sup> Immunodiagnostic tests continue to evolve, and the use of genus-specific antigens is likely to improve diagnostic accuracy.<sup>74,118,119</sup> Other attempts to improve the specificity of immunodiagnosis have used IgG subtype antibody levels instead of total IgG. Subtype analysis of antibody responses to excretory-secretory antigens such as the cathepsin protease (cathepsin L1) demonstrated that the predominant subtypes induced in human infections are IgG<sub>1</sub> and IgG<sub>4</sub>, consistent

with a predominant type 2 T-cell response.<sup>120–124</sup> The detection of subtype-specific antibodies in ELISAs may improve the specificity of the diagnostic immunoassays and make it possible to distinguish recent from remote infections.<sup>125</sup>

In chronic biliary fascioliasis, the diagnosis is made on finding *F. hepatica* eggs in stool specimens or at the time of surgery for bile duct obstruction when eggs or adult flukes are removed from the biliary tree. Because egg production tends to be low, it is advisable to examine multiple stool specimens. The formalin–ethyl acetate concentration technique appears to be less sensitive than the AMS iii (Tween 80) method or the Weller-Dammin modification method.<sup>72,126</sup> Eggs of *F. hepatica* can be confused with those of the intestinal flukes *Fasciolopsis buski* and echinostomes. Recovery of adults after anthelmintic treatment will allow species identification. False-positive “spurious” stool results can occur after consumption of liver of infected animals and can be ruled out by repeated stool examinations.

## TREATMENT AND VACCINATION

Triclabendazole, a benzimidazole, is now the drug of choice as a single 10 mg/kg oral dose or two doses 12 hours apart. Bioavailability is increased when triclabendazole is taken with food.<sup>127,128</sup> Efficacy has been as high as 92% in humans, but significant resistance has been seen both in animal and in vitro studies and repeat treatment may be necessary.<sup>129–131</sup> The most frequent side effect was colicky abdominal pain between days 3 and 7 posttreatment, compatible with fluke expulsion through the bile ducts.

Unlike other trematodes, *F. hepatica* is frequently resistant to praziquantel, although some studies have shown effectiveness.<sup>74,87,94,132–136</sup> Animal studies show a lack of effectiveness of praziquantel against both immature and adult flukes in cattle and sheep. In the past bithionol has been considered the drug of choice at a dosage of 30 to 50 mg/kg/day in three divided doses on alternate days for 10 to 15 days.<sup>137–139</sup> More than one course may be necessary. Side effects are mild and include anorexia, nausea, vomiting, abdominal pain, and pruritus.

Acute ascending cholangitis must be treated with antibiotics and surgery. A patient with a severe acute hepatic stage may benefit from the short-term use of systemic steroids.<sup>140</sup> Other drugs used in the past include emitine, dehydroemetine, chloroquine, albendazole, and mebendazole, but all have been dropped because of toxicity or lack of effectiveness.<sup>72,77</sup>

Fasciola is one of few trematodes for which vaccines have been developed and used to protect against veterinary disease. The *F. hepatica* cathepsin-L protein, an important virulence determinant that was identified as a dominant antigen in excreted-secreted proteins, is a first-generation vaccine.<sup>141</sup> There have been a number of trials using this molecule in cattle and sheep, with protection against challenge infection ranging from 38% to 79%.<sup>94,141–143</sup> In natural and experimental infections, *F. hepatica* induces a polarized Th2 response as evidenced by the generation of IgG<sub>1</sub> but little or no IgG<sub>2</sub> antibody subtypes, whereas vaccination induces antibody responses to cathepsin-L, the immunogen, that include high titers of both IgG<sub>1</sub> and IgG<sub>2</sub>, indicating a mixed Th1/Th2 response.<sup>94,124,144</sup> These observations have been interpreted to indicate that protection is associated with a Th1 or a mixed Th1/Th2 response.<sup>94,124</sup> However, some vaccine trials with the same antigen have demonstrated

little or no protection, suggesting that other factors, such as adjuvant and antigen formulation, may be important in generating protective immune responses.<sup>145</sup> No vaccines have yet been developed for human infections.

## ■ LUNG FLUKES

### INTRODUCTION

Lung flukes are members of the genus *Paragonimus* and while more than 40 species have been described, only eight are presently considered of human importance. Most of the 40 species are parasites of animals, and some may be synonymous. Twenty-eight are considered distinct species, with 21 from Asia, 2 from Africa, and 5 from the Americas; most are in tropical areas.<sup>146</sup>

*P. westermani* is the best-known species and is found in humans and animals throughout the East, from India to Japan and the Philippines. *P. heterotremus* is reported from China and Southeast Asia, *P. skrjabini* and *P. hueitungsensis* from China, *P. miyazakii* from Japan, *P. uterobilateralis* and *P. africanis* from central and western Africa, *P. mexicanus* from Central and South America, and *P. kellicotti* from North America.<sup>1,147,148</sup>

### AGENT

*P. westermani* was first found in a Bengal tiger that died in an Amsterdam zoo and was named after the zoo director, G. F. Westerman. The first human infection was found in a Portuguese sailor who died in Taiwan in 1879. He had earlier been a patient of Patrick Manson's in Amoy, China, and Manson later concluded that the hemoptysis seen in this man and his Chinese patients was due to this parasite.<sup>149</sup>

Adult *P. westermani* is reddish-brown in color, coffee bean-shaped, 7 to 16 mm in length, 4 to 8 mm in width, and 5 mm thick. The integument is spiny, and the anterior and ventral suckers are of equal size (Fig. 117-4A).

The eggs are yellow-brown in color, thick-shelled with a large operculum, and measure 80 to 120  $\mu\text{m}$   $\times$  50 to 65  $\mu\text{m}$  (Fig. 117-4B). The eggs embryonate in water, and the miracidia hatch in 3 weeks and search for specific snail hosts. Development in snails yields free-swimming cercariae, which penetrate a crab or crayfish second intermediate host and encyst as metacercariae. When these are eaten raw, partially cooked, pickled, or salted, the metacercariae excyst and penetrate the intestinal wall of the definitive hosts and enter the peritoneal cavity. The larval worms remain here for several days, then cross the diaphragm, and enter the pleural cavity and eventually the lung parenchyma to mature to adults in 2 months. A fibrotic cyst wall develops around paired (or tripled) adults, but eggs that are produced escape through cyst-bronchial fistulas and are coughed up in sputum or swallowed and passed in the feces.

Other species of *Paragonimus* have life cycles similar to *P. westermani* but develop in different snail and crustacean intermediate hosts. Species differentiation is based on adult fluke rather than egg morphology.

### EPIDEMIOLOGY

*Paragonimus* transmission occurs most notably in China (*P. westermani*, *P. skrjabini*, *P. heterotremus*, and *P. hueitungsensis*), Korea (*P. westermani*), Japan (*P. westermani*, *P. miyazakii*), Vietnam (*P. heterotremus*), Cameroon (*P. africanus* and *P. uterobilateralis*), Ecuador (*P. mexicanus*), and Peru (*P. mexicanus*).<sup>1</sup> Yet the range of each of the species includes

*Paragonimus* spp.

**FIGURE 117-4** *Paragonimus westermani*. A, Adult (size 7 to 16 × 4 to 8 mm). B, Egg (size 80 to 120 × 50 to 60 μm). (From Orihel TC, Ash LR: *Parasites in Human Tissues*. Chicago, ASCP Press, 1995.)

many other countries. As an example, *P. westermani* is endemic to China, Japan, Korea, Taiwan, and the Philippines, and the parasite has also been found in Nepal, Bangladesh, Myanmar, Laos, Kampuchea, Vietnam, Thailand, Papua New Guinea, and the former USSR.<sup>146,147</sup> *P. uterobilateralis*, while most prevalent in Cameroon, is found from Zambia west to Guinea. *P. mexicanus* is found from Mexico south to Peru and Ecuador.<sup>1</sup>

In China, human disease caused by *P. westermani*, *P. skrjabini*, and *P. heterotremus* has been reported from 21 provinces with prevalences of up to 10.4% in some areas. Stool examination surveys of 146,698 people from seven prefectures between 1954 and 1968 yielded an egg-positive rate of 10.4%. Control programs in China had reduced the parasitosis to an estimated 1000 persons infected in 1991. In Korea, a national skin test survey revealed an overall prevalence of 13% in 1959. Control measures, disruption of the ecosystem, and pollution have reduced crab and crayfish populations, and only 16 of 16 million stools were egg-positive in 1990.<sup>1</sup> Taiwan had several endemic foci in the past, but today human infections are rare owing to changes in eating habits and the effect of water pollution and industrialization on the intermediate hosts.<sup>150</sup> Fewer than 300 human cases of paragonimiasis have been reported from a few areas of the Philippines, although infected crustaceans are easily found in endemic areas.<sup>147</sup> Little epidemiologic information is available from other countries reporting this parasitosis. Despite the reductions in Southeast and East Asia, it has been estimated that there are 20.5 million cases worldwide.<sup>1,70</sup>

More than 15 species of snails in the families Hydrobiidae, Thiaridae, and Pleurocercidae serve as the first intermediate hosts of *P. westermani*. The important second intermediate hosts are crabs in the genera *Eriocheir*, *Potamon*, and *Sundathelphusa*, and crayfish of the genus *Cambaroides*. Individuals become infected by eating these crustaceans raw or insufficiently cooked.

The range of culinary artistry is wonderful. In China there is wine-soaked freshwater crab, crayfish curd, raw crab juice, and crab jam; in Thailand, raw freshwater shrimp salad or crab sauce; in Korea, raw crab in soy sauce; in the Philippines, roasted or raw crabs and crab juice seasoning. Crabs and crab juice have been used for medicinal purposes.<sup>148</sup>

*Paragonimus* species can infect many mammalian species, but some will not mature in these hosts beyond the larval stage. When humans consume these paratenic hosts, the larvae survive stomach acid and penetrate the small intestine wall, completing their life cycle in the human host. Paratenic wild boars have served as a source of infection when eaten raw.<sup>151</sup>

## DISEASE

The different *Paragonimus* species each appear to have a different disease spectrum. *P. westermani* represents one clinical pole, with, most commonly, pleuropulmonary disease and relatively infrequent extrapulmonary disease. *P. heterotremus*, *P. africanus*, and *P. uterobilateralis* appear to be similar in presentation to *P. westermani*.<sup>151–154</sup> The other clinical pole, represented by *P. skrjabini*, is mainly extrapulmonary, with cutaneous lesions the most frequent clinical presentation. Pulmonary disease tends to be caused by adult flukes and cutaneous disease by immature flukes. It is thought that host-fluke species compatibility helps determine which clinical pole a particular species will produce.<sup>1,155,156</sup>

## Acute Paragonimiasis

After an incubation period of between 2 and 15 days, the initial symptoms are diarrhea and abdominal pain, followed several days later by fever, chest pain, fatigue, urticaria, eosinophilia, or cough, or any combination of these, lasting several weeks.<sup>155,157</sup>

\*Palm civets, cats and dogs can also rarely serve as definitive hosts in the Far East and in W. Africa. *P. miyazakii* has been acquired by eating uncooked wild boar meat. *P. kellicotti* infection has occurred in US. Other species include *P. skrjabini*, *heterotremus*, *africanus*, *uterobilateralis*, *mexicanus*.

### Pleuropulmonary Paragonimiasis

Although acute paragonimiasis may occur, most infections are either silent or insidious in onset. The initial clinical presentation occurs early in the 5- to 10-year life span of the adult fluke, but in some cases it may occur many years after acquisition of the infection.<sup>158,159</sup>

In *P. westermani* infections, the initial presentation is often an abnormal chest film in an asymptomatic patient. Early clinical symptoms include cough or chest pain. The cough, initially dry, often becomes productive of viscous and rusty-colored or blood-tinged sputum and appears to be worsened by exertion.<sup>160</sup> The sputum may be peppered with rusty-brown flecks consisting of clumps of eggs.<sup>2</sup> Charcot-Leyden crystals are frequent. Occasionally there is profuse hemoptysis following

paroxysmal coughing. The chest pain is often pleuritic. Fevers are infrequent and in spite of a prolonged clinical history the patient's health usually remains relatively unimpaired. Eosinophilia may be present initially but is usually absent in chronic infections.

Radiographic findings include pulmonary lesions such as focal, segmental, or lobar air space consolidation, small cysts (5 to 30 mm), calcified spots, linear opacities, or nodules. The earliest infiltrates and nodules may show some limited migration.<sup>158,161</sup> About 10% to 40% of egg-positive patients will have normal chest films.<sup>158</sup> As the fluke matures, cavitary lesions of 1- to 4-cm diameter are seen; as the fibrotic reaction increases with time they appear as nodules, but their cavitary nature and associated burrow tracts of 0.5- to 1.0-cm diameter can be

visualized by CT scan. Eventually these lesions are replaced by oval to round calcifications.<sup>158</sup> Bronchoscopy, other than as a means of retrieving eggs, does not reveal any diagnostic findings.<sup>158</sup>

Pleural lesions have been found in 5% to 71% of patients in different clinical series of *P. westermani* infections and include effusions, hydropneumothorax, and pleural thickening, which can be bilateral.<sup>158,159,162</sup> The frequency of pleural disease appears to be greatest in *P. skrjabini* infections.<sup>155</sup> Pleural fluid is sterile, contains a leukocyte count over 1000/ $\mu$ L, many eosinophils, and elevated protein and lactate dehydrogenase (LDH) and decreased glucose values. Eggs are rarely found in sputum or pleural fluid.

Excised pulmonary lesions reveal a wide variety of histopathologic changes characterized by the presence of adult worms within fibrous cysts up to 1.5 cm in size, juxtaposed and often communicating with bronchioles or bronchi. Egg-induced granulomas are easily confused with tuberculosis. Adjacent to the cysts are bronchiectases, various pneumonic processes, and vasculitis. Both acute and chronic cellular reactions can coexist within the same lesions.<sup>159,160,163</sup>

### Extrapulmonary Paragonimiasis

A percentage of patients with paragonimiasis will develop lesions in locations other than the lung. The frequency is dependent on the species of *Paragonimus*, the intensity of the infection, and possibly the duration. The diagnosis of these ectopic infections depends on the organ involved; cerebral infection produces the most frequent morbidity.

### Cerebral Paragonimiasis

Cerebral paragonimiasis is the most frequent form of extrapulmonary disease diagnosed, possibly reflecting the sensitivity of the central nervous system (CNS) to such an insult rather than a predilection of the parasite for that site. Cerebral involvement occurs in less than 1% of cases in community-based studies and up to 24% in hospital-based studies.<sup>164</sup> Cerebral paragonimiasis most often occurs in younger age groups; 90% of patients are less than 30 years of age.<sup>165</sup> Clinical findings in cerebral paragonimiasis are extremely varied, since they are dependent on the location of the parasite. They reflect parasite-induced meningitis, arachnoiditis, and cerebral and spinal space-occupying lesions. Meningitis tends to be acute in onset and to be the initial presentation of cerebral paragonimiasis in up to a third of cases. Intracerebral lesions occur usually in occipital or temporal lobes, or both. The clinical presentation, which tends to be insidious in onset, includes a history of seizures (80%), visual disturbances (60%), headache (55%), motor weakness (48%), sensory disturbances (40%), and vomiting (33%). Seizures are often focal motor initially, progressing to grand mal as the disease evolves.<sup>165,166</sup> Physical findings include ophthalmologic abnormalities (75%), a decline in mental function (70%), hemiparesis (60%), and hemihypoesthesia (45%). Pulmonary paragonimiasis is seen in the majority of cases of CNS disease and, in fact, precedes CNS involvement in two thirds of patients.

Plain films show calcifications and characteristically aggregated, round or cyst-like soap bubbles in more than 40%

of patients. Common CT and MRI findings are conglomerated, multiple ring-shaped enhancing lesions with surrounding edema, described as grape clusters.<sup>142</sup> These rings are usually smooth and round, but may, at times, be irregular in outline. They are usually 1 to 3 cm in diameter and have contents with a density equal to or slightly greater than that of cerebrospinal fluid (CSF). At times hemorrhages up to 4 cm in diameter are associated with the ringlike structures, or the lesions may be nodular. Calcifications can be punctate, round, cystic, or amorphous and will increase in frequency with the duration of disease.<sup>164,165,167</sup>

### Cutaneous Paragonimiasis

Although a cutaneous presentation is uncommon in *P. westermani* infections, it has been reported to occur in 80% of infections due to other species of *Paragonimus* (e.g., *P. skrjabini*, *P. miyazakii*). The cutaneous presentation, which has been called trematode larva migrans, consists of painless and migratory subcutaneous swellings or subcutaneous nodules on the trunk and proximal extremities.<sup>168,169</sup> There is often a peripheral blood eosinophilia, which can be extreme.

### Miscellaneous Sites

Flukes, usually immature, may come to rest in ectopic intra-abdominal sites such as the liver, spleen, peritoneum, intestinal wall, or mesenteric lymph nodes. The clinical picture reflects the site and can include abdominal pain, diarrhea, and even dysentery.

## PATHOGENESIS AND IMMUNITY

As with other tissue-dwelling trematodes, infection with *P. westermani* is also associated with eosinophilia and leukocytosis in the early stages of infection, reflecting activation of the immune system. Eosinophil infiltration around the sites of egg deposition is a consistent pathologic feature, as is eosinophilia and an elevated IgE level, indicative of a Th2 cell-regulated response.<sup>170</sup> IgG<sub>4</sub> antibodies predominate among anti-*Paragonimus* antibodies. However, it remains to be determined whether Th2 lymphocytes play an important role in resistance to the parasite.<sup>170</sup> In rodent models, excreted-secreted products of *Paragonimus* appear to regulate the innate and adaptive immune response in the host, by mechanisms such as attenuating the survival and function of eosinophils, and secreting pro-inflammatory cytokines and chemokines.<sup>171–174</sup> However, these immune mechanisms have been studied only in rodent and bovine models of paragonimiasis, and their roles in human infections have not been elucidated.

## DIAGNOSIS

Pulmonary paragonimiasis must be suspected in persons from known endemic areas when a chronic cough is present; the most important differential diagnoses are tuberculosis, bronchiectasis, and chronic bronchitis. The diagnosis is almost always made by finding the characteristic eggs in sputum, stool, gastric aspirates, or tissue. Examination of blood-streaked sputum is the most productive. Egg detection in sputum may

require repeated examinations, and a 24-hour sputum collection can increase the sensitivity.<sup>175</sup> This collection is centrifuged, the sediment dissolved in 3% sodium hydroxide, and then examined for eggs.<sup>147</sup> In children and the elderly, in whom sputum swallowing is more frequent, the examination of stool and gastric aspirate specimens can be more productive. Ziehl-Neelsen stains of specimens for mycobacteria may destroy the fluke eggs, making separate examinations necessary.<sup>161</sup> In patients who have pleural or CNS involvement, it is very uncommon to find eggs in pleural fluid or CSF aspirates.

### Immunodiagnosis

Most immunologic tests used in the diagnosis of paragonimiasis employ crude extracts of flukes.<sup>114</sup> The CF test has been a standard test for years. This test is sensitive and becomes negative 6 to 12 months after cure, making it useful for following therapy.<sup>176,177</sup> Some cross-reactivity with other trematode parasites has been noted, particularly in the chronic phase of paragonimiasis.<sup>178</sup> A skin test using extracts of adult *Paragonimus* is useful for screening in epidemiologic surveys because of its high sensitivity (80% to 90%), but it remains positive 10 to 20 years after cure.<sup>179</sup> ELISAs for detection of antibodies to *P. westermani* are both sensitive (92%) and highly specific (greater than 90%), but require longer (4 to 24 months) to become positive after infection and longer to normalize after cure.<sup>180–183</sup> Crude worm extracts do not provide an acceptably specific ELISA.<sup>184,185</sup> Consequently, the most sensitive ELISA to date has been developed by Centers for Disease Control and Prevention (CDC; sensitivity, 96%; specificity, 100%), using an 8-kD component of *P. westermani* as the antigen.<sup>186</sup> Recently, antigen detection assays have been developed that utilize mixtures of monoclonal antibodies to capture *P. westermani* antigens from serum, with a sensitivity approaching 100% and specificity greater than 95%.<sup>187,188</sup> The utility of these assays in the field remains to be evaluated, but they would likely provide as sensitive a measure of active infections in field surveys as is found in individuals.

### TREATMENT

Praziquantel is the drug of choice because of minimal side effects and the short course of administration. A treatment of 75 mg/kg/day in three divided doses for 2 days is 90% to 100% effective.<sup>158,160,189,190</sup> Symptoms improve within 2 to 3 days, although radiologic findings may worsen for the first 10 days.<sup>161</sup> Adverse effects are mild and include headache, intestinal symptoms, and transient urticaria. Large pleural effusions may require drainage. Surgical intervention may be required for long-standing effusions (years) or empyemas (months).<sup>158</sup>

Triclabendazole, a drug recently introduced as therapy for fascioliasis, successfully treats pulmonary paragonimiasis at a dosage of 5 mg/kg daily for 3 days or 10 mg/kg bid for one day.<sup>191</sup> Bithionol, available in the recent past, could cure 92% of pulmonary cases at a dosage of 40 mg/kg/day on alternate days for 10 to 15 doses.<sup>192</sup> Gastrointestinal side effects in 70%, dermatologic side effects in 21%, and the duration of treatment are recognized limitations.

Untreated pulmonary paragonimiasis can resolve in 5 to 10 years, leaving dysfunction commensurate with the degree of scar tissue produced in the pleura or lungs.<sup>158</sup>

## ■ INTESTINAL FLUKES

About 70 trematode species are reported to inhabit the human intestinal tract. Knowledge of their clinical presentation is limited even for those that affect relatively large populations.<sup>1,193</sup> The best known are *Fasciolopsis buski*; the Heterophyidae, including *Heterophyes heterophyes* and *Metagonimus yokogawai*; and several *Echinostoma* species. The intestinal flukes are thought to produce no symptoms except when present in very large numbers, which is a rare occurrence. Few cause serious disease, but community-based and case-control studies have yet to be done. Most of these flukes occur in Asia, but foci of these infections occur in other populations throughout the world. They are usually localized in areas where there are freshwater snail vectors and animal reservoir hosts and occur in people with particular dietary habits.<sup>194</sup>

### FASCIOLOPSIS BUSKI

#### AGENT

*F. buski*, the giant intestinal fluke, was first found, by Busk, in an Indian sailor in London in 1843. The parasite is found in China, Taiwan, Thailand, Laos, Bangladesh, India, Indonesia, Vietnam, Myanmar, and Kampuchea. The worm is elongated, oval, and fleshy, measuring 20 to 75 mm × 8 to 20 mm × 0.5 to 3.0 mm. Eggs are large, operculate, and unembryonated when passed, and measure 130 to 140 μm × 80 to 85 μm. The miracidia develop in several weeks, hatch from the eggs, and infect planorbid snail intermediate hosts. After development in the snail, cercariae emerge and encyst as metacercariae on aquatic plants. When the plant is eaten, the attached metacercariae excyst and attach to the small intestinal mucosa. The prepatent period is 3 months, and the worms are known to live for 6 or more months in the human. Pigs and dogs act as reservoirs (see following discussion).

#### EPIDEMIOLOGY

Several planorbid snails serve as the first intermediate host of *F. buski*; these usually live in muddy ponds and streams, including those found adjacent to slaughterhouses where feces from pigs contaminate the waters. Snails and edible water plants also flourish in these waters. The metacercaria of *F. buski* can attach to most aquatic plants, including water caltrop (*Trapa bicornis*, *Trapa natans*), water chestnut (*Eliocharis tuberosa*), water bamboo (*Zizania aquatic*), water hyacinth (*Eukhornia crassipes*), water morning glory (*Ipomoea aquatic*), watercress (*Nasturtium officinale*), lotus (*Nymphaea lotus*), and others.<sup>1,195</sup> These plants may be cultivated near homes in water contaminated accidentally or fertilized intentionally with human or pig feces. Pigs are a major reservoir host, but there are some areas where humans are infected while pigs are not. Both ingested plants and water contaminated with detached metacercariae are

sources of infection. Children eating plants during play, especially in rural areas, have the highest prevalence rates.

## DISEASE

This large fluke attaches to the duodenal and jejunal mucosa and produces focal inflammation, ulceration, and small abscesses at the sites of attachment. However, community-based studies reveal no clinical or biochemical differences between lightly to moderately infected cases and controls.<sup>196</sup> Early symptoms, which begin 30 to 60 days after exposure, are epigastric pain, mimicking peptic ulcer disease, and diarrhea.<sup>197</sup> Hunger or anorexia, nausea, and vomiting may occur. Rarely, in heavy infections, edema of the face, abdominal wall, and legs; ascites; and severe prostration have been described.<sup>198</sup> The cause of these is not understood. Large numbers of flukes may cause focal ileus or intermittent obstruction. Eosinophilia is variable but may be marked.<sup>199</sup>

## HETEROPHYIDS (HETEROPHYES SPP., METAGONIMUS SPP., ETC.)

There are a large number of small intestinal flukes less than 2.5 mm long in humans, other mammals, and birds in the families Heterophyidae, Plagiorchiidae, Lecithodendridae, Microphallidae, and others. The flukes in the Heterophyidae are the most prevalent and best studied.

## AGENTS

Of at least 10 human species of intestinal fluke in the family Heterophyidae the three most prevalent are *Heterophyes heterophyes*, *H. nocens*, and *Metagonimus yokogawai*. Bilharz described the first, *H. heterophyes*, at the autopsy of a native of Cairo. These are the smallest of the human flukes. They measure 1 to 2 mm in length, are oval to pear-shaped, and have spiny integuments. The eggs are operculate, ovoid, and yellowish in color, measure 27 to 30  $\mu\text{m} \times 15$  to 17  $\mu\text{m}$ , and are very difficult to speciate. The eggs are embryonated when passed and are ingested by a snail intermediate host. Cercariae from the snail enter freshwater fish, encyst as metacercariae, and, when eaten raw, excyst and complete their development to adult flukes within 1 to 2 weeks in the small intestine of humans, other mammals, and fish-eating birds. The prepatent period is only 9 days and the parasite may live for a few months to a year in the final host.

## EPIDEMIOLOGY

The highest infection rates for *H. heterophyes* have been reported in Egypt, Iran, and Sudan; for *M. yokogawai*, in Korea, China, Taiwan, Indonesia, Russia, and Japan; and for *H. nocens*, in Korea and Japan. However, there have been reports of these and other heterophyid species in scattered locations around the world, the greatest number occurring in Asia and Southeast Asia. Distributions of the different Heterophyidae greatly overlap. In Korea, of 19 different intestinal flukes reported in humans, 12 are different heterophyid species.<sup>200</sup> The heterophyids are parasites of fish-eating mammals and birds, which, like humans, acquire the infection by

eating raw or incompletely cooked freshwater or brackish water fish.

The overall prevalence of *M. yokogawai* in Japan is low (0.2% to 0.3%), but in some areas the prevalence is high (51% to 75%).<sup>201</sup> In Korea, *M. yokogawai* infection rates of 1% to 2% have been reported for the population as a whole, reaching 29% along some coastal streams.<sup>200</sup> Infection rates of *M. yokogawai* in Taiwan and the Philippines are around 1%.<sup>202</sup>

*H. heterophyes* infects the gray mullet *Mugil cephalus* in the brackish lagoons of Egypt's Nile delta. Infection rates can reach 65% in children in villages where these fish are traditionally eaten raw.

## DISEASE

Nine days on average following ingestion of the metacercaria, dyspepsia, colicky abdominal pain, diarrhea, and eosinophilia may occur.<sup>203,204</sup> A mild focal inflammatory reaction and superficial erosions are produced at the site of attachment.<sup>2</sup> The flukes appear to live for less than a year. The fluke may penetrate the mucosa, and eggs may embolize from these intramucosal sites via lymphatics to the systemic vascular system. Eggs of three different heterophyid species have been recovered from capillaries of brain, heart, lungs, spleen, and liver, where space-occupying granulomatous lesions induce clinical pathology.<sup>204–207</sup> Myocarditis can follow the occlusion of myocardial vessels by eggs and the resultant granulomatous and fibrotic host reaction. Thickened mitral valves containing ova have been reported.<sup>208</sup>

## ECHINOSTOMA SPECIES

### AGENT

These trematodes are primarily parasites of birds and mammals but are common among certain populations of Asia. Fifteen species have been reported in humans. The parasites are elongate, tapered at both ends, and 5 to 15 mm  $\times$  1 to 2 mm in size. The name derives from a collar of spines in two rows surrounding the oral sucker. The anterior integument is also provided with tiny spines. Eggs are operculate, thin-shelled, and vary in size (83 to 130  $\mu\text{m} \times 58$  to 90  $\mu\text{m}$ ).<sup>47</sup> The eggs embryonate in freshwater in 14 days, and the miracidia enter the snail host. Cercariae emerge from the snail and encyst in the same snail from which they emerged or in other snails, clams, fish, or tadpoles, which serve as second intermediate hosts. Any of these, if eaten uncooked, infect the human final host.<sup>209</sup>

## EPIDEMIOLOGY

The most common of the 15 reported *Echinostoma* species in humans are *E. ilocanum* in the Philippines and Thailand, and both *E. malayanum* and *E. revolutum* in Thailand.<sup>1,210</sup> In northern Luzon in the Philippines, *E. malayanum* infection rates have averaged 10% of surveyed populations, with highs of over 40%.<sup>150</sup> In northern Thailand, a variety of echinostomes infect humans with prevalence rates as high as 50%.<sup>211</sup> These and the other species are found at lower prevalences in Southeast Asia, eastern and South Asia, and also in Egypt and Central and South America.<sup>193</sup> The major source of infection

with *E. ilocanum* is the snail *Pila conica*, which is eaten uncooked in parts of the Philippines. Other sources of infections are clams, tadpoles, frogs, and fish, all serving as second intermediate hosts for echinostomes. Rats, dogs, cats, birds, and other fish-eating animals are reservoirs of infection.

## DISEASE

These flukes attach to small intestinal mucosa, producing inflammatory lesions and shallow ulcers at the sites of attachment. A self-infection by ingestion of 113 metacercaria of *Echinochasmus japonicus* resulted, after 10 days, in abdominal pain and diarrhea.<sup>1,212</sup> There are no clinical epidemiology studies, but it is generally accepted that symptoms are rare in any but the heaviest infections (approximately 500 flukes), which are uncommon.<sup>47,213</sup> The presentation may include colicky abdominal pain and loose bowel movements and at times diarrhea and eosinophilia.

## MISCELLANEOUS INTESTINAL FLUKES

There are many other intestinal flukes within the preceding families—Fasciolidae, Heterophyidae, and Echinostomatidae. They have more limited distributions and are less well studied. Two flukes in two other families, Troglotremitidae and Paramphistomatidae, are worth mentioning.

*Nanophyetus salmincola* is a small fluke found in eastern Siberia and the northwestern coast of North America. It belongs to the same family, Troglotremitidae, as does *Paragonimus*. Adults are 0.8 to 2.5 mm × 0.3 to 0.5 mm, and eggs are 64 to 97 μm × 34 to 55 μm in size. Fish, such as salmon, are the second intermediate hosts. Intestinal symptoms can occur with heavy infections in a manner similar to that of other intestinal flukes. More unusually, this fluke is a vector for the rickettsial organism *Neorickettsia helminthoeca*, which produces a fatal illness in dogs (“salmon poisoning”).<sup>214,215</sup>

*Gastrodiscoides hominis* is a piriform intestinal fluke that is 8 to 14 mm × 5 to 8 mm in size and produces eggs that measure 150 μm × 60 to 70 μm. It is widely distributed from India to the Philippines and north to Kazakhstan. The human colon can be colonized, with resultant mucoid diarrhea. Pigs and rodents appear to be the reservoir.

## DIAGNOSIS

Since clinical presentations are nonspecific, indications that infections are present are, at times, eosinophilia, a particular dietary history, and the time interval since possible infection; *H. heterophyes* and *M. yokogawai* do not survive in the intestine for more than a year. The diagnosis is made on stool examination or by tissue biopsy or necropsy. Egg identification can be very difficult because many of the intestinal fluke eggs have similar morphology and overlapping sizes. Overlapping “small” fluke eggs include *H. heterophyes* (28 to 30 μm × 15 to 17 μm), *M. yokogawai* (26 to 28 μm × 15 to 17 μm), *C. sinensis* (28 to 35 μm × 12 to 19 μm), and *O. viverrini* (30 μm × 12 μm). Overlapping “large” fluke eggs are *Fasciolopsis buski* (130 to 140 μm × 80 to 85 μm), *Echinostoma* spp. (83 to 130 μm × 58 to 90 μm), and *Fasciola hepatica* (130 to 150 μm × 60 to 90 μm). As well, there are many other less

common intestinal flukes with focal distribution that produce similarly sized eggs.

Examination of stools for expelled adult flukes after treatment with praziquantel is necessary to make a definitive diagnosis. Although praziquantel may damage the integument of the adult fluke, it is still often possible to make a species identification.

## TREATMENT

Evidence from limited trials suggests that praziquantel is highly effective against intestinal flukes at 15 to 25 mg/kg given in a single dose.<sup>1,216</sup> The new benzimidazole, triclabendazole, at 5 mg/kg twice daily after a meal at a 6- to 8-hour interval for 1 day, shows promise in the treatment of intestinal flukes.<sup>1</sup> Alternative drugs include for *F. buski*, niclosamide 40 mg/kg/day for 1 to 2 days (maximum daily dose of 4 g); for *H. heterophyes*, niclosamide 1000 mg in a single dose; and for *Echinostoma* spp., albendazole 400 mg twice daily for 3 days.<sup>47,204,217</sup>

## PREVENTION AND CONTROL

Prevention and control of food-borne trematode infections require changes in habits that have been in practice for generations.<sup>218</sup> These habits are variably dependent on attitudes, education, poverty, environmental degradation, food security, and other factors, and control strategies will have to take all these into account. Education can change habits. Such education should include understanding of the impact of the use of human and animal feces as fertilizer for aquatic plants and fishponds. Methods of food preservation must be addressed, since many foods deteriorate quickly in the tropics, and smoking, pickling, and fermentation methods often do not destroy metacercariae. Irradiation may offer an alternative.<sup>219</sup> Preservation by cooking can be difficult in many heavily populated regions where fuel is scarce. On the other hand, some populations prefer to eat raw food, aware of the nutritional value of raw foods.<sup>1</sup>

National strategies are necessary to control these parasites. Health education and appropriate regulations, both for water bodies used for pisciculture and aquatic plant crops, can have an impact. Mass treatment programs using praziquantel or triclabendazole may be beneficial but require more experience.<sup>220</sup> Molluscicide or elimination of the animal host reservoirs does not appear to be realistic over the long term.<sup>1</sup>

# Arthropods, Tongue Worms, Leeches, and Arthropod-borne Diseases

JEROME GODDARD

## INTRODUCTION

Arthropods (phylum Arthropoda), characterized by a chitinous exoskeleton, segmented bodies, and jointed appendages, may negatively affect human health in a number of ways. There may be direct effects, such as bites and stings; indirect effects, such as disease transmission; and perceived effects, such as entomophobia or delusions of parasitosis (see Chapter 135). Only a small percentage of all arthropod species are medically important, most being benign in their association with humans. An even smaller percentage are true human parasites—a few mite and lice species. However, especially in tropical regions, many human illnesses are either caused by or transmitted by arthropods.

Nothing better exemplifies the dynamic nature of the natural world than do the diseases transmitted by insects and other arthropods—the vector-borne diseases. For example, malaria, once on the decline, now affects hundreds of millions of people annually. In fact, the malaria situation is worsening due to development of insecticide resistance in mosquitoes and drug resistance in parasites. Dengue fever is expanding geographically and inflicts pain and suffering on millions of people annually (see Chapter 72). There are even new or emerging vector-borne diseases. Lyme disease was virtually unknown 30 years ago but now occurs at the rate of about 20,000 reported cases per year in the United States alone. Human tick-borne ehrlichiosis in the United States was first reported in 1986. There have been at least 1000 cases since then. Recent evidence indicates that there may be several *Ehrlichia* and tick species involved in this disease.

To understand and control outbreaks of these diseases requires knowledge of ecology and medical entomology not commonly encountered in today's world of molecular biology and medical specialization. This chapter provides classic

medical entomology information in a brief, but readily accessible form.

## PARASITIC ARTHROPODS

Although most bloodsucking arthropods (e.g., mosquitoes, ticks) could be considered “parasites” since they derive nourishment at the expense of other organisms, in this discussion the term *parasitic arthropods* is limited to human parasites that live most of their lives on or in the host. Lines of demarcation are not clear, but the parasites chosen to be included here are the human lice, a couple of skin-inhabiting mites, and a few flesh-dwelling fly larvae.

## Lice

Two species of sucking lice (insect order Phthiraptera, previously known as Anoplura) are parasites of humans—head and body lice both being varieties of one species, *Pediculus humanus*, and pubic lice, *Phthirus pubis* (Figs. 118-1 and 118-2). Neither head nor pubic lice are involved in disease transmission, but body lice may carry the agents of epidemic typhus, trench fever, and louse-borne relapsing fever.<sup>1</sup> Body and head lice look almost identical, but head lice remain more or less on the scalp and body lice on the body or in clothing. Head and body lice are tiny (1 to 4 mm long), elongated, soft-bodied, light-colored, wingless insects with gradual metamorphosis—that is, the young look like the adults, only smaller. They are dorsoventrally flattened (top to bottom, as opposed to fleas, which are flattened side to side), with an angular ovoid head, and a nine-segment abdomen. The head bears a pair of simple lateral eyes and a pair of short five-segment antennae. Head lice live on the skin among the hairs of the patient's head. Eggs (nits) are laid at the base of shafts of hair. Body lice live primarily in the clothing of infested persons, but move to the body occasionally for a blood meal.

Head lice are transmitted among humans by close contact such as hugging or sharing of personal items such as hats, scarfs, or combs. Body lice are transmitted also by close contact, but more so by sharing infested clothing. Since neither head nor body lice usually survive more than 24 to 48 hours off their hosts, pesticidal fogging or spraying of entire homes and schools is not indicated. Pediculicidal lotions or shampoos, combined with washing of garments and bedding, will usually eliminate the infestation.

Pubic lice (crab lice) occur almost exclusively in the pubic or perianal areas, rarely on eyelashes, eyebrows, or other coarse-haired areas. They are not as active as head or body lice, being attached more often to the skin. Thus, pubic lice may often be confused with nymphal (immature) ticks. Pubic lice generally cannot survive more than 24 to 48 hours off their human hosts and therefore do not inhabit rugs, carpets, pets, or bathrooms. Although it is theoretically possible to obtain the infestation from inanimate objects such as toilet seats, most transmission occurs from sexual contact. In fact, pediculosis pubis is rightly categorized as a sexually transmitted disease (see Chapter 132). One study reported that

**FIGURE 118-1** Head louse (left) and pubic louse (right). (From U.S. Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control and Prevention, pictorial keys.)

one-third of patients with pubic lice may have other sexually transmitted diseases.<sup>2</sup> Treatment involves pediculicidal lotions and shampoos for the patient, as well as all family members and sexual contacts of the patient.<sup>3</sup>

### Mites

Scabies mites (acarine order Astigmata), *Sarcoptes scabiei*, infest human skin causing intense itching and sometimes a generalized rash. Scabies occurs worldwide, affecting all races and socioeconomic classes. The mites are very tiny (0.2 to 0.4 mm long), oval, saclike, eyeless specimens with rudimentary legs (Fig. 118-3). Scabies mites are transmitted by close human-to-human contact with infested persons. The mites burrow under the skin, leaving tiny open sores and linear serpiginous burrows (tracts) that contain the mites and their eggs. Sensitization is the cause of the itching, erythema, and rash.

Scabies should be confirmed by finding the mites in a skin scraping, since other forms of dermatitis may resemble scabies. Finding the mites is often not as easy as it seems and an experienced dermatologist may be needed. Treatment involves scabicial creams or lotions applied per package instructions. Some commonly used products today are lindane (Kwell), permethrin (Elimite), and crotamiton (Eurax).<sup>1</sup> For crusted or Norwegian scabies developing in immunocompromised patients (see Chapter 133), therapy is with a single dose of ivermectin given at 200 µg/kg orally and repeated after

**FIGURE 118-3** Scabies mite.

2 weeks, if needed.<sup>4</sup> Ivermectin may have specific utility in treating scabies in institutional or community outbreaks.<sup>3,5</sup> Since the mites cannot live off a human host for more than 24 hours or so, pesticidal treatment of rooms, schools, and so on is unnecessary.

Dog or horse scabies is also caused by races of *S. scabiei*, but these mites cannot complete their life cycle in human skin. Humans can acquire dog scabies, causing itching and papular or vesicular lesions, primarily on the waist, chest, or forearms. However, removal or treatment of the source of infestation (i.e., infested dog or horse) will lead to gradual resolution of the human case.

Follicle mites (acarine order Prostigmata) are minute, wormlike mites that infest humans. Two species may be found. *Demodex folliculorum* lives in the hair follicles and *Demodex brevis* in the sebaceous glands. Although some researchers have attributed various pathologic conditions to *Demodex* infestation, the mite is basically a harmless saprophyte. The mites are approximately 0.1 to 0.4 mm long, have vestigial legs, and transverse striations over much of the body. They most commonly occur on the forehead, the malar areas of the cheeks, the nose, and the nasolabial fold, but may occur anywhere on the face or around the ears. Most people acquire *Demodex* from maternal contacts in early childhood.

### Parasitic Fly Larvae

Myiasis is the infestation of human or animal tissues by fly larvae (insect order Diptera). It may be accidental (e.g., eating eggs or larvae), facultative (e.g., eggs laid on malodorous or festering wounds), or obligate (e.g., necessary for fly development—true parasitism).<sup>6</sup> Accidental myiasis is mostly a benign event, but the larvae could possibly survive temporarily, causing stomach pains, nausea, or vomiting. Facultative myiasis may result in considerable pain and tissue damage as fly larvae leave necrotic tissues and invade healthy tissues. Obligate myiasis can be serious or even fatal, as fly larvae feed in healthy tissues.

**FIGURE 118-2** Body louse next to paper clip.

**FIGURE 118-4** Syrphid fly larva involved in a case of urinary myiasis. (From Goddard J: Direct injury from arthropods. Lab Med 25:365–371, 1994. Copyright © American Society of Clinical Pathologists.)

**FIGURE 118-6** Third-stage *Dermatobia hominis* larva. (Courtesy of Dr. Tom Brooks.)

### Species Involved in Facultative Myiasis

Numerous species of house flies (Muscidae), blow flies (Calliphoridae), and flesh flies (Sarcophagidae)—all in the insect order Diptera—have been implicated in facultative myiasis (Fig. 118-4). Some notorious offenders are the blow fly, *Phaenicia sericata*, the rat-tailed maggot, *Eristalis tenax*, the black blow fly, *Phormia regina*, and the house fly, *Musca domestica*.<sup>7</sup> In addition, the latrine fly, *Fannia scalaris*, has often been associated with urinary or rectal myiasis.

### Species Involved in Obligate Myiasis

The human bot fly, *Dermatobia hominis*, is a parasite of humans, cattle, swine, cats, dogs, horses, sheep, and other mammals and a few birds in Mexico and Central and South America. The larvae feed under the skin, causing often episodically painful, swollen, draining cutaneous lesions with a typical air-pore. Although this parasite does not occur in the United States, numerous cases are seen by U.S. physicians as a result of people returning from cruises or vacations to endemic areas (see Chapter 126).

The adult fly (about 15 mm long) resembles a large bluish blow fly (Fig. 118-5). It has a yellowish or brown head and legs. Adult bot flies catch various bloodsucking flies (often a

mosquito) and attach eggs to their sides. The carrier flies subsequently feed on a human, cow, or other host at which time the newly hatched bot fly larvae penetrate the host skin. The larvae vary in appearance depending upon stage of development (Figs. 118-5 and 118-6), usually do not move laterally within the skin, and may feed for 4 to 10 weeks. When mature, larvae exit the lesion, drop to the soil, and pupate. Treatment involves direct removal of the maggots (by excision or otherwise) and antibiotics to prevent or control secondary infection.

Screwworm flies are also obligate parasites of living flesh, feeding for the entire larval period inside a host. Natural hosts include domestic and wild mammals, as well as humans. Human infestations have resulted from the flies ovipositing on or near a wound, or sometimes inside the nostril while a person sleeps in the daytime. Upon hatching, the larvae begin feeding, causing extensive tissue destruction. There is an Old World species, *Chrysomya bezziana*, a species of tropical Africa and Asia, and a New World species, *Cochliomyia hominivorax*, which at one time was distributed from the southern United States to southern Brazil (Fig. 118-7). Fortunately, due to a sterile male release program, the New World species no longer occurs in the United States. Treatment of screwworm myiasis involves removal of the larvae. Surgery may be

**FIGURE 118-5** Human bot fly. A, First-stage larva. B, Second-stage larva. C, Third-stage larva. D, Adult fly. (From U.S. Department of Agriculture, Miscellaneous Publication No. 631.)

**FIGURE 118-7** Screwworm flies. A, Adult female *Chrysomya bezziana*. B, Larva of *C. bezziana*. C, Adult female *Cochliomyia hominivorax*. D, Larva of *C. hominivorax*. (From U.S. Department of Agriculture, Miscellaneous Publication No. 631.)

required if larvae cannot be removed via natural orifices. Since eggs are laid in batches, there could be tens or even hundreds of maggots in a wound.

The Tumbu fly, *Cordylobia anthropophaga*, is a major cause of cutaneous myiasis in tropical Africa. The larvae burrow into subcutaneous tissues creating a boil-like lesion with a serous exudate. Children are most commonly affected, with lesions occurring on areas of the body covered with clothing since the flies oviposit on soiled clothing. The adult fly has a yellow-brown body and is about 6 to 12 mm long. Full-grown larvae are 13 to 15 mm long. The larvae exit their furuncular lesions after about 8 to 10 days. Treatment involves direct removal of the maggots, surgically if necessary, and treatment to prevent or control secondary infection. *Wohlfahrtia magnifica*, one of the sarcophagid flies, is an obligate parasite in the wounds and natural orifices of mammals, including humans. It occurs over the warmer parts of Europe, Asia, northern Africa, the Middle East, and the Mediterranean region. *Wohlfahrtia* behavior is similar to that of a screwworm fly, in that it oviposits—actually depositing larvae instead of eggs—on tiny skin lesions such as scratches, tick bites, and such or mucous membranes. The developing larvae feed for 5 to 7 days, exit the host, fall to the ground, and pupate. *Wohlfahrtia* flies look similar to flesh flies (Sarcophagidae), but instead of a checkerboard pattern on the abdomen they have round spots. *W. magnifica* occurs over the warmer parts of Europe, Asia, northern Africa, the Middle East, and the Mediterranean region.

*W. magnifica* infestations are difficult to treat because of the (usually) numerous aggressively feeding larvae within the nose or existing wounds. Irrigation or possible surgical exploration to remove the larvae is needed.

## INJURIOUS ARTHROPODS

### Stinging Arthropods

The insect order Hymenoptera contains ants, wasps, and bees.<sup>8</sup> Most stinging wasps and some bees are solitary or sub-social insects; they primarily use their stings to subdue prey. Rarely does this offensive use of stinging and venom lead to human envenomization. These venoms do not cause much pain or swelling. Social wasps, bees, and ants, however, sting for defensive purposes, and their venom causes intense pain. Workers of these groups instinctively defend their nests and readily sting intruders coming too close to their nests. Social hymenopterans include yellow jackets, honeybees, paper wasps, and fire ants (Figs. 118-8 and 118-9). All stings generally cause pain, itching, wheal, flare, and other symptoms, which resolve in a couple of hours unless there are enough stings (several hundred) to produce a direct toxic reaction. Allergic systemic reactions include cutaneous manifestations (e.g., urticaria, angioedema), bronchospasm, edema of the upper airway, and hypotensive shock, and range from mild to life-threatening.<sup>9</sup> Even if a person is not allergic to the venom, toxic effects from hundreds of stings can occur, including histamine release (nonallergic), contraction of smooth muscle, increase in capillary permeability, vasodilation with accompanying drop in blood pressure, and hemolysis.<sup>10</sup>

Some caterpillars can sting. Both mechanical irritation and injection of venom by the caterpillar spines or hairs contribute to the urticarial response in humans. Upon exposure, these structures may be broken, allowing venom to either be injected into the skin or to ooze out onto abraded skin. I reported observations from a caterpillar sting case that included erythema, small papules, throbbing pain, and axillary

**FIGURE 118-8** Typical stinging insect (yellow jacket). (From U.S. Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control and Prevention, pictorial keys.)

pain resulting from venom travel to local lymph nodes.<sup>11</sup> Allergic reactions from caterpillars may occur just like those from other stinging arthropods.<sup>12</sup>

Urticating caterpillars include the Io moth, *Automeris io*; the brown-tail moth, *Euproctis chrysorrhoea*; the buck moth, *Hemileuca maia*; the puss caterpillar, *Megalopyge opercularis*; the saddleback caterpillar, *Sibine stimulea*, and many others (Fig. 118-10). Treatment may include ice packs and oral administration of antihistamines to relieve the itching and burning sensation. Acute urticarial lesions may be relieved by application of topical corticosteroids. For severe pain associated with stings, meperidine HCl, morphine, or codeine is sometimes used. Systemic allergic reactions such as hypotension

**FIGURE 118-10** Some stinging caterpillars. A, Lo moth. B, Puss caterpillar. C, Saddleback caterpillar. (Adapted from U.S. Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control and Prevention, pictorial keys.)

and bronchospasm are usually treated with epinephrine, antihistamines, and other supportive measures.

Scorpions (arachnid order Scorpiones) are eight-legged, generally flattened arthropods with two apparent body regions—a broad seven-segment mesosoma and a narrow five-segment metasoma terminating in a sting (Fig. 118-11). Many scorpions pose no serious health hazard, but several species have venom sufficiently toxic to kill a human (outright, not an allergic reaction). Systemic effects from such stings include drowsiness, spreading partial paralysis, muscle twitching, profuse salivation, perspiration, hypertension, tachycardia, and convulsions. In the United States, the only dangerous species, with the exception of allergic reactions to the venom, is *Centruroides exilicauda* (formerly *C. sculpturatus*) of the southwestern United States, especially Arizona. The fat-tailed

**FIGURE 118-9** Bumblebee.

**FIGURE 118-11** Typical scorpion.

scorpion, *Androctonus australis*, is a notoriously dangerous scorpion of northern Africa and the Middle East. *Buthus occitanus* is a widely distributed, dangerous scorpion composed of several subspecies that is found in southern France, Spain, Italy, Greece, several Mediterranean islands, Israel, Jordan, and northern Africa. Treatment of scorpion stings is somewhat controversial.<sup>13</sup> For the dangerous species, some advocate prompt use of antivenin. Others take a wait-and-see approach since many scorpion sting cases resolve on their own in a few hours. Severe cases usually occur in children and are characterized by agitation and other systemic symptoms. Hospitalization for close monitoring and supportive care is required in such cases.

### Allergic Reactions to Insect Stings

Some people develop hypersensitivity to arthropod venoms; allergic reactions to stings can be roughly grouped into two categories—large local and systemic reactions.<sup>9</sup> Large local reactions are characterized by painful, pruritic swelling of at least 5 cm in diameter and may involve an entire extremity. However, there are no systemic symptoms far removed from the sting site. Usually only about 5% of those people who experience large local reactions will develop anaphylaxis upon future stinging events. Systemic reactions produce symptoms in areas other than the sting site. These are serious clinical manifestations characterized by urticaria, angioedema, respiratory difficulty, gastrointestinal distress, and hypotension. Sometimes a severe allergic reaction results in anaphylactic shock within 15 to 30 minutes. Persons who experience a generalized allergic reaction (even mild) may be at risk of a severe reaction and possible death upon the next sting, days, weeks, or months later. For this reason, persons who have any type of large local or systemic reaction to a sting (or bite, for that matter) should see an allergist for possible immunotherapy and prescription of autoinjectable epinephrine.<sup>9</sup>

### Biting Arthropods

The bed bug (insect order Hemiptera), *Cimex lectularius*, is a bloodsucking human pest that causes itching and inflammation from its bites (Fig. 118-12). Bed bugs have occasionally been found that are naturally infected with disease organisms such as those causing anthrax, plague, and typhus. However, they are not considered vectors of these disease agents.<sup>14</sup> Adult bugs are oval-shaped (approximately 5 mm long), flattened insects that somewhat resemble immature cockroaches. They are reddish-brown in color; the immature bed bugs are yellowish-white. Bed bugs are found in temperate regions worldwide. A related species, *Cimex hemipterous*, occurs in the tropics. The bugs hide in cracks and crevices during the day, usually on or near the host's bed, and feed at night, taking blood from their host for 5 to 10 minutes. Bites from bed bugs are generally self-limited and require little specific treatment other than antiseptic or antibiotic creams or lotions to prevent infection.

Horse flies and deer flies (insect order Diptera) are notorious pests of horses, cattle, deer, dogs, and humans. They have scissors-like mouthparts and can inflict painful bites. Although no human illnesses have been associated with horse flies, deer flies can transmit the agents of tularemia and loiasis in Africa (see Chapter 99).<sup>6</sup>

**FIGURE 118-12** Bed bug. (Copyright © 2002 by Jerome Goddard, PhD, Mississippi Department of Health, Jackson, MS.)

Horse flies look like giant, robust house flies (15 to 25 mm long) with large prominent eyes (Figs. 118-13 and 118-14). Deer flies, also in the family Tabanidae, are much smaller (8 to 15 mm long) and have dark patterned wings. Many deer fly species have a gray or yellow-gray body with various arrangements of spots on the abdomen. Numerous species of both groups occur almost worldwide, where they breed in moist or semiaquatic sites such as margins of ponds, damp earth, or other sites containing mud and water. The wormlike larvae spend their entire developmental time in these muddy habitats. Adult females seek a blood meal, whereas males may feed on flower nectar. Except for secondary infections, requiring appropriate antibiotics, horse fly and deer fly bites are generally few and self-limited. Biting midges (insect order Diptera) are extremely small, delicate flies that bite people, especially near coastal areas. They are also sometimes referred to as “no-see-ums,” “punkies,” or “biting gnats.” The midges are so small that people often remark, “something is biting me, but I can’t see what it is.” Other than the severe biting nuisance,

**FIGURE 118-13** Adult horse fly. (From Yearbook of Agriculture, Washington, DC, U.S. Dept of Agriculture, 1952.)

**FIGURE 118-14** Horse fly.

biting midges are generally of no medical significance to humans. Numerous species of biting midges occur in temperate and tropical areas over much of the world. A notorious pest, *Culicoides furens*, is a vicious biter, occurring near salt marshes along the Atlantic, Pacific, and Gulf Coasts. In California, *Leptoconops torrens* and *Leptoconops carteri* are very bothersome. Biting midges are usually gray in color and extremely small (0.6 to 1.5 mm). They may have clear or hairy wings which fold scissors-like over the abdomen at rest. Larval stages of biting midges develop in organic detritus along the bottom of shallow areas of water or in water-saturated soil. Adults are generally active only in the warmer months of the year. Simple antipruritics are generally the only treatment needed for biting midge bites. Avoidance of midge-infested areas at or near dark (e.g., salt marshes), and repellents containing DEET are the best course of action for those affected by biting midges.<sup>15,16</sup>

Numerous species of spiders (arachnid order Araneae) bite people, but the hobo spiders, violin spiders, and widow spiders may be a significant medical threat.<sup>1,17</sup> Violin spiders have a necrotic venom affecting cutaneous tissues. The brown recluse spider, *Loxosceles reclusa*, is perhaps the most important member of the group, although other violin spiders producing necrotic lesions also occur in the United States and elsewhere. Brown recluse spider bites are usually localized, sometimes producing considerable necrosis that may result in an unsightly scar (Figs. 118-15 and 118-16). The bite may be painless at first, but becomes very painful within 8 hours. Healing may require several months. Systemic reactions to brown recluse spider bites may occur, including hematuria, anemia, rash, fever, coma, and cyanosis. Death may occur but is rare. The adult spider is tan to dark brown with a 2- to 4-cm leg span (Fig. 118-17). Six eyes, arranged in a semicircle of three pairs, are on top of the head and a characteristic violin-shaped marking (base forward) extends from the eyes to the beginning of the abdomen. The brown recluse spider may be found from Minnesota to Maine, south to Florida, and west to Arizona and Wyoming. It is most common in the south-central United States. The spider is frequently found indoors in bathrooms, bedrooms, cellars, attics, cardboard boxes, and

**FIGURE 118-15** Brown recluse spider bite in early stages of necrosis. (From Goddard J: Physician's Guide to Arthropods of Medical Importance, 4th ed. Boca Raton, FL, CRC Press, 2002.)

storage areas. Outdoors, it may occur in sheds or barns and in piles of rocks or firewood. Treatment of brown recluse spider bites is symptomatic and quite controversial. Current therapies include ice, antibiotics, and the leukocyte inhibitor dapsone.<sup>1,18-20</sup> Controlled studies are lacking and dapsone may produce hemolysis, so it should be used under careful supervision.

Widow spiders, in contrast to violin spiders, have a neurotoxic venom that produces systemic pain, weakness, tremor, muscle spasm, and tightness in the chest. Often patients exhibit a rigid, boardlike abdomen. There is rarely a significant lesion at the bite site. Paralysis, stupor, and convulsions may occur in severe cases, with an occasional fatality. Several widow spiders occur in North America—all with similar appearance. *Latrodectus mactans* is the species most generally associated with the name "black widow spider" and the female has a red

**FIGURE 118-16** Brown recluse spider bite approximately 3 months post bite. (From Jarratt JH, Gaydon DG, and Goddard J, Mississippi Cooperative Extension Service, Publication No. 2154, Mississippi State, MS.)

**FIGURE 118-17** Adult brown recluse spider. (Courtesy of Dr. James Jarratt, Mississippi Cooperative Extension Service, Mississippi State, MS.)

or orange hourglass-shaped marking on the underside of the abdomen (Fig. 118-18). There is considerable variation in these red markings, with some species having red dots or hash marks on the top and bottom of the abdomen. Widow spiders are found in protected places such as water or gas meter housings and piles of rocks, boards, bricks, or firewood. Inside, they are often found in garage corners; dark, undisturbed cabinets; or underneath appliances. Treatment of *Latrodectus* envenomization includes application of ice, symptomatic treatment of muscle spasms and pain, and (possibly) antivenin in severe cases.

**FIGURE 118-18** Female black widow spider underside showing hourglass-shaped marking. (Courtesy of Dr. James Jarratt, Mississippi Cooperative Extension Service, Mississippi State, MS.)

Children, the elderly, and persons with other medical conditions of risk may need hospitalization and close monitoring.

Centipedes (arthropod class Chilopoda), sometimes called “hundred-leggers,” are long multisegmented arthropods with one pair of legs per body segment (Fig. 118-19). They are flattened, fast-moving creatures that can inflict a painful bite. Bites are generally harmless, but often produce two red and swollen puncture wounds. Rarely, systemic symptoms such as anxiety, vomiting, irregular pulse, dizziness, and headache may occur. Most of the smaller centipede species are harmless, but larger species (especially in the genus *Scolopendra*) in the southern United States and tropics can inflict a painful bite. Treatment includes washing the bite site with soap and water, application of ice, and analgesics for pain.

Numerous mite species (arachnid subclass Acarina), while not parasitic on humans, will bite, causing itch or dermatitis (Fig. 118-20). Examples are the bird and rat mites, which will bite if in close proximity to people. People may also be bitten as a result of occupational exposure to products containing chicken mites, straw mites, or grain mites. The tropical rat mite, *Ornithonyssus bacoti*, is an ectoparasite of rats that is widely distributed on most continents. The tropical fowl mite, *Ornithonyssus bursa*, is similar in habits to the tropical rat mite, except it is found on domestic and wild birds. One of the most common mites causing human dermatitis in poultry houses, farms, ranches, and markets where chickens are sold is the chicken mite, *Dermanyssus gallinae*. The chicken mite occurs worldwide and may also infest English sparrows, starlings, and other birds. Straw itch mites, *Pyemotes tritici*, will bite people as they come into contact with infested straw, hay, grasses, oats, or peas. The grain and flour mites (several species) may cause grocer’s itch, copra itch (coconuts), and other itches. Grain and flour mites occur worldwide. Treatment of mite bites primarily involves alleviation of symptoms, and avoidance or eradication of the mites. Since none of these mite species take up permanent residence on human

**FIGURE 118-19** Centipedes and millipede. A, House centipede. B, Large southwestern United States centipede. C, Millipede. (From U.S. Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control and Prevention, pictorial keys.)

**FIGURE 118-20** A, Tick. B, Mite. (From U.S. Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control and Prevention, pictorial keys.)

skin, elimination of the source of mite exposure should be the main objective. Competent pest control operators (exterminators) are often helpful in finding and eliminating bird's nests or rat's burrows in and around the home.

Chigger mites (acarine order Prostigmata), also sometimes called "harvest mites" or "red bugs," although not truly parasitic on humans, are actually the six-legged larval stage of trombiculid mites. The adults do not bite. Chiggers cause intense itching and irritation, and some species are involved in the transmission of the scrub typhus rickettsia (see Chapter 52) in the Far East.<sup>1</sup> Chigger larvae are very tiny (0.2 mm long), round mites with numerous setae. Although barely visible to the human eye, they look orangish or reddish when placed on a white background. Numerous chigger species occur in various parts of the world, where they utilize a wide range of vertebrate hosts. They reach their hosts by crawling up on blades of grass or leaves. On humans, they generally crawl into and attach to where clothing fits snugly or where flesh is tender. They do not actually bite, but insert their mouthparts at a pore or base of a hair follicle where they feed for a couple of days. The feeding process is irritating and produces erythematous itchy patches on affected areas of skin. Treatment often includes an antiseptic, hydrocortisone, anesthetic (benzocaine) solutions, or ointments to minimize itching and reduce the possibility of secondary infection.

### Other Forms of Injury

Blister beetles (insect order Coleoptera) may cause blistering on human skin when touched or handled. The beetles contain the blistering agent cantharidin in their body fluids, which is released when they sense danger. Cantharidin penetrates human skin readily, producing blisters in a matter of hours. Many species of blister beetles exist in the United States, most in the family Meloidae, although a few beetles in the Staphylinidae family cause blisters. Three of the most common are the ash gray and striped blister beetles in the central and southeastern United States, and the oil beetles (consisting of several species) in the southwestern states. In Europe, three important blister beetles are *Paederus limnophilus*, *Paederus gemellus*, and *Lytta vesicatoria*, the Spanish fly of southern Europe. Blisters resulting from blister beetle exposure are usually not serious, with reabsorption occurring in a few days if the blisters are unruptured.<sup>21</sup> The skin may flake if the blisters

have ruptured, leaving an area of mild erythema for a week or so.<sup>19</sup> Affected areas should be washed with soap and water and bandaged until the blisters reabsorb. Antibiotic ointments or creams may help prevent secondary infection.

Millipedes (arthropod class Diplopoda), also sometimes called "thousand-leggers," are slow-moving elongate, worm-like arthropods (see Fig. 118–19C). They are somewhat similar to centipedes except they have two pairs of legs on most body segments and are generally rounded instead of flattened. Millipedes are commonly found in soft, decomposing plant materials. Although millipedes neither bite nor sting, some species secrete defensive body fluids that may discolor and burn human skin. Treatment involves washing the exposed area with copious amounts of water as soon as possible. Some medical personnel have recommended using solvents such as ether or alcohol to remove the noxious fluids. Eye exposure requires a thorough irrigation with warm water and consultation with an ophthalmologist.

House dust mites (acarine order Astigmata) indirectly affect human health by producing allergic reactions in some people. The mites do not bite or sting, but a considerable amount of allergic rhinitis, asthma, and childhood eczema is attributable to their presence in the human environment.<sup>22</sup> Adult house dust mites are whitish, plump, very tiny (0.5 mm) mites with fine striations on their cuticle. They are most often associated with furniture on which people spend a lot of time—mattresses, sofas, and recliners. House dust mite allergy is often managed by immunotherapy using mite extracts and by minimizing the level of mites in the patient's home.<sup>22</sup> Carpets may need to be replaced with tile or wood floors. Feather pillows should be replaced with synthetic ones. Plastic covers are available for mattresses.

### ARTHROPOD VECTORS OF DISEASE

Arthropods that are capable of transmitting disease organisms to vertebrate hosts are called vectors. For example, mosquitoes in the genus *Anopheles* are vectors of malaria (see Chapter 90). Interestingly, no other mosquitoes are able to acquire and transmit the malaria parasites. In disease outbreaks there are primary vectors (the main species involved in disease transmission) and secondary vectors (the species that may occasionally become involved under certain conditions). An understanding of how disease agents are acquired and transmitted by arthropods is crucial to preventing and managing vector-borne diseases. Mechanical transmission of disease agents occurs when arthropods just physically carry pathogens from one place or host to another host—often via body parts. For example, flies and cockroaches have numerous hairs, spines, and setae on their bodies which collect contaminants as the insects feed on dead animals or excrement (Fig. 118-21). When they subsequently walk on food or food preparation surfaces, mechanical transmission occurs. Mechanical transmission may also occur if a blood-feeding arthropod has its feeding interrupted. For example, if a mosquito feeds briefly on a viremic bird and is interrupted, a subsequent feeding (if immediate) on a second bird may result in virus transmission.

In biologic transmission, there is either multiplication or development of the pathogen in the arthropod, or both (Fig. 118-22). Biologic transmission is often classified into three types. In *cyclodevelopmental transmission* the pathogen

**FIGURE 118-21** One example of mechanical transmission of disease organisms.

must undergo a cycle of development within the arthropod vector, but no multiplication. For example, the filarial worm that causes bancroftian filariasis (see Chapter 98), when first ingested by mosquitoes, is not infective to a vertebrate host; it must undergo a period of development. *Propagative transmission* means the pathogen must undergo multiplication before transmission can occur. There is no cyclic change or

development of the organisms—plague bacteria in fleas, for example (see Chapter 42). Finally, in *cyclopropagative transmission* the pathogen must undergo both cyclic changes and multiplication. The classic example is malaria plasmodia in *Anopheles* mosquitoes (see Chapter 90). The following discussion relates to some of the arthropod species involved in biologic transmission of disease agents.

**FIGURE 118-22** Biologic transmission: enzootic and epizootic transmission cycles of plague bacillus. (U.S. Air Force drawing courtesy of Dr. Chad P. McHugh.)

**FIGURE 118-23** Kissing bug. (From U.S. Department of Health, Education, and Welfare, Public Health Service, Centers for Disease Control and Prevention, pictorial keys.)

Kissing bugs (insect order Hemiptera) have an elongate, cone-shaped head and are often called “cone-nose bugs” (Fig. 118-23). They are called kissing bugs because their blood meals are occasionally taken near the lips at night. Other sites of frequent attack are the hands, arms, and feet. Kissing bugs may transmit the causative agent of Chagas’ disease, or American trypanosomiasis (*Trypanosoma cruzi*) in Mexico and Central and South America (see Chapter 93). Several species of kissing bugs are capable of transmitting the agent. However, four are considered principal vectors: *Panstrongylus megistus*, *Rhodnius prolixus*, *Triatoma infestans*, and *Triatoma dimidiata*. These bugs occur most commonly in poor, underdeveloped areas with dilapidated or poorly constructed huts or shacks. Infection is not by salivary secretions associated with the bite but by fecal contamination of the bite site. Treatment of kissing bug bites involves washing the bite site with soap and water, and application of topical palliatives. Oral antihistamines may help relieve itching.<sup>23</sup> Occasionally, systemic allergic reactions result from kissing bug bites. Those cases may be treated like any other sting or bite allergic reaction.

**FIGURE 118-24** Male hard tick showing ornamentation. (U.S. Air Force photograph courtesy of Bob Burnes.)

Ticks (acarine order Ixodida) are efficient vectors of bacteria, viruses, rickettsiae, and protozoans. At least 14 human diseases are caused or transmitted by ticks (Table 118-1). The most recent addition to this list—American boutonneuse fever—was only recently discovered as a “disease within a disease” because the new clinical entity was apparently hidden within cases diagnosed as Rocky Mountain spotted fever (RMSF).<sup>24,25</sup> Major tick-borne diseases in the United States are Lyme disease (approximately 20,000 cases per year; see Chapter 45), Rocky Mountain spotted fever (approximately 600 cases per year; see Chapter 50), and ehrlichiosis (approximately 100 cases per year). Two types of tick-borne ehrlichiosis (see Chapter 53) are now recognized—human monocytic ehrlichiosis (HME), caused by *Ehrlichia chaffeensis*, and human granulocytic anaplasmosis (HGA), caused by *Anaplasma phagocytophilum*.

Two families of ticks occur over much of the world: the hard ticks, Ixodidae, and the soft ticks, Argasidae. Hard ticks resemble huge mites and have anteriorly attached mouthparts visible dorsally (see Fig. 118-20A). They often have white or shiny markings (Fig. 118-24); they attach firmly to their hosts

**Table 118-1** Major Tick-borne Diseases

Disease	Causative Agent	Tick Vectors
Lyme disease	Spirochete	<i>Ixodes ricinus</i> complex
Human monocytic ehrlichiosis	Rickettsia	<i>Amblyomma americanum</i>
Human granulocytic anaplasmosis	Rickettsia	<i>Ixodes scapularis</i> , others
Rocky Mountain spotted fever	Rickettsia	<i>Dermacentor variabilis</i> , <i>Dermacentor andersoni</i> , others
American boutonneuse fever	Rickettsia	<i>Amblyomma maculatum</i> , others
American babesiosis	Protozoan	<i>I. scapularis</i>
Colorado tick fever	Virus	Primarily <i>D. andersoni</i>
Tularemia	Bacterium	<i>A. americanum</i> , <i>D. variabilis</i> , <i>Dermacentor nuttalli</i> , <i>I. ricinus</i>
Boutonneuse fever	Rickettsia	<i>Rhipicephalus sanguineus</i> , <i>Rhipicephalus appendiculatus</i> , others
Tick paralysis	Salivary toxin	<i>D. andersoni</i> , <i>D. variabilis</i> , <i>Ixodes holocyclus</i>
Tick-borne encephalitis	Virus	<i>I. ricinus</i> , <i>Ixodes persulcatus</i> , <i>Dermacentor marginatus</i> , others
Relapsing fever	Spirochete	Several soft tick <i>Ornithodoros</i> spp.
Crimean-Congo hemorrhagic fever	Virus	<i>Hyalomma marginatum</i> , <i>Hyalomma anatolicum</i> , others
Siberian tick typhus	Rickettsia	Primarily <i>D. marginatus</i> , <i>Dermacentor silvarum</i> , <i>D. nuttalli</i>

**FIGURE 118-25** Seed tick bites, 4 days post attachment. (From Goddard J: *Physician's Guide to Arthropods of Medical Importance*, 4th ed. Boca Raton, FL, CRC Press, 2002.)

for several days. The females are capable of enormous expansion. Soft ticks are leathery without hardened plates, and their mouthparts are not visible dorsally. They do not remain firmly attached to their hosts (as larvae sometimes do), but instead feed only for approximately 15 to 30 minutes. Soft ticks are reclusive and not commonly seen or recognized by people. There are three motile life stages of hard ticks: larva, nymph, and adult. Larvae are extremely small (1 mm) and are often called seed ticks. Seed ticks of some species, especially *Amblyomma americanum* and *Amblyomma cajennense*, will feed on a wide variety of animal hosts and often get on people by the thousands, causing itching and irritation (Fig. 118-25). Nymphs (approximately 2 mm in size) also require a blood meal and some species will feed on humans. Adult ticks feed on various vertebrates, depending upon the tick species; some are specific to a certain host, whereas others are indiscriminate.

The Lone Star tick, *A. americanum*, is an important species distributed from central Texas, east to the Atlantic Coast, and north to approximately Iowa and New York. It also occurs in the northern states of Mexico. Other than nuisance effects from biting, the Lone Star tick is a known vector of the agents of tularemia and ehrlichiosis (HME).

The deer tick, *Ixodes scapularis*, is the principal vector of *Borrelia burgdorferi*, the causative agent of Lyme disease in the eastern United States. It also transmits anaplasmosis (HGA) and babesiosis. Most tick researchers now consider *Ixodes dammini* (occurring in the Northeast and upper Midwest) the same as *I. scapularis*. Thus all references to the northern form now use *I. scapularis*.<sup>26</sup>

The American dog tick, *Dermacentor variabilis*, is another species of medical importance in the United States. It is the

primary vector of the agent of RMSF in the East, a vector of tularemia, and may cause tick paralysis. The American dog tick occurs throughout the United States except in parts of the Rocky Mountains region.

Generally, no treatment is needed for tick bites other than palliatives after tick removal. Tick removal methods vary greatly. A study by J.H. Theis<sup>27</sup> advocated tick removal by the use of tweezers or protected fingers using a steady retracting pressure. Needham<sup>28</sup> evaluated five methods commonly used for tick removal: (1) petroleum jelly, (2) fingernail polish, (3) 70% isopropyl alcohol, (4) a hot kitchen match, and (5) forcible removal with tweezers. He found that the commonly advocated methods are either ineffective, or, worse, actually created greater problems. If petroleum jelly or some other substance causes the tick to back out on its own (and most often it does not), the cement used for attachment surrounding the mouthparts remains in the skin where it continues to cause irritation. Touching the tick with a hot match may cause it to burst, increasing the risk of disease germ exposure. Furthermore, hot objects may induce ticks to salivate or regurgitate infected fluids into the wound. "Unscrewing" a tick is likely to leave broken mouthparts in the host's skin. Needham recommended the following procedure for tick removal: (1) use blunt forceps or tweezers; (2) grasp the tick as close to the skin surface as possible (Fig. 118-26) and pull upward with steady, even pressure; (3) take care not to squeeze, crush, or puncture the tick; (4) do not handle the tick with bare hands because infectious agents may enter via mucous membranes or a break in the skin; (5) after removing the tick, thoroughly disinfect the bite site and wash hands thoroughly with soap and water.<sup>28</sup>

Mosquitoes (insect order Diptera) are the most significant, medically important arthropods worldwide, causing annoyance and transmitting disease to humans and a host of other animals (Fig. 118-27). Besides the disease threat, the nuisance effect of mosquito bites can be unbearable, leaving many geographic areas undeveloped. Only a relatively few of the 3000 or so mosquito species are significant vectors of human disease, but mosquito-borne diseases are major health problems (Table 118-2). Mosquitoes are small flies with long, 15-segment antennae, a long proboscis for bloodsucking, and scales on their wings. Due to the pattern of wing scales, some mosquitoes may appear to have spots on their wings (Fig. 118-28). Female mosquitoes take a blood meal and subsequently lay eggs on or at a water source. The water source varies, depending on the mosquito species, but includes swamps, flooded areas, tree holes, and artificial containers such as cans, discarded tires, and the like. The larvae develop in their aquatic habitat for one or more weeks after which they pupate and eventually emerge as adult mosquitoes.

Numerous species in the genus *Anopheles* are vectors of the malaria organism. Notorious members of the genus are the *A. gambiae* complex in Africa, *A. albimanus* in Central and South America, and the *A. minimus* complex in Southeast Asia.<sup>1</sup> There are at least three efficient malaria vectors in the United States—*A. quadrimaculatus*, *A. hermsi*, and *A. freeborni*. Other major mosquito-borne diseases are yellow fever, dengue fever, filariasis, and numerous encephalitis viruses. *Aedes albopictus* and *Aedes aegypti* are the primary vectors of yellow fever and dengue. Various species in the genera *Culex*,

**FIGURE 118-26** Recommended method of tick removal. (From U.S. Air Force Publication No. USAF-SAM-SR-89-2.)

*Mansonia*, *Psorophora*, and others transmit the agents of filariasis and mosquito-borne encephalitis, such as West Nile virus.

Other than the disease transmission threat, treatment of mosquito bites is generally unnecessary. Exceptions may include topical corticosteroids or antibiotic creams to prevent secondary infection (especially in children), and hypersensitivity reactions to the bites themselves. People highly sensitive to mosquito bites may safely reduce the cutaneous reactions to bites by prophylactic treatment with nonsedating antihistamines such as cetirizine<sup>29</sup> and DEET-containing insect repellants are effective.<sup>15,16</sup>

Fleas (insect order Siphonaptera) constitute a major human health threat because of their ability to transmit the causative agents of plague (see Chapter 42) and murine typhus (see Chapter 51). They may also serve as intermediate hosts of the dog tapeworm, *Dipylidium caninum*. Fleas are small, laterally flattened, wingless insects that take a blood meal from a wide variety of animal hosts. Some species are

extremely host-specific, only biting a particular rodent or bat, or other animal. Others are indiscriminate, feeding on most any mammal (some attack birds also). The cat flea, *Ctenocephalides felis*, is one of the most important fleas in North America, feeding on several domestic and wild animal species, causing severe annoyance. Most fleas found on dogs in the United States are cat fleas. The oriental rat flea, *Xenopsylla cheopis*, is an ectoparasite of Norway rats and roof rats and is the primary vector of plague and murine (endemic) typhus. The cosmopolitan human flea, *Pulex irritans*, occurs on a wide range of host animals, especially pigs. The chigoe flea, *Tunga penetrans*, burrows into the skin (especially toes) of people in tropical and subtropical regions. Flea bites may be treated with topical corticosteroids and antibiotics if secondary infection is a problem. Tungiasis (tropics) may require excision of the embedded fleas.

Sand flies (insect order Diptera) are small, delicate blood-sucking flies that somewhat resemble tiny mosquitoes. Though not commonly recognized by most people, sand flies are significant vectors of the disease agents of leishmaniasis (see Chapter 94), bartonellosis (see Chapter 40), and sand fly fever (see Chapter 69). Sand flies are tiny (3 mm), golden, brown, or gray long-legged flies. They hold their wings in a V when at rest. Instead of scales (like mosquitoes) on the wing margins, these flies have hairs. Numerous species occur almost worldwide. *Phlebotomus caucasicus*, *Phlebotomus papatasi*, *Phlebotomus longipes*, and *Phlebotomus pedifer* are efficient sand fly vectors of dermal leishmaniasis in the Old World. *Phlebotomus argentipes* is the chief vector of visceral leishmaniasis in many parts of the Old World. *Lutzomyia longipalpis* is a major vector in the New World. Sand fly fever vectors are primarily *P. papatasi* and *Phlebotomus sergenti*. Bartonellosis is transmitted by *Lutzomyia verrucarum*. Other than disease transmission concerns, treatment of sand fly bites generally only involves palliative antipruritic lotions or creams.

Tsetse flies (insect order Diptera), including several species in the genus *Glossina*, are vectors of trypanosomes of

**FIGURE 118-27** Female mosquito taking bloodmeal. (Centers for Disease Control and Prevention photo, Atlanta, GA)

**Table 118-2** Some Major Mosquito-borne Diseases

Disease	Causative Agent	Mosquito Vectors
Malaria	Protozoan (4 species)	Numerous <i>Anopheles</i> spp.
Dengue fever	Virus	<i>Aedes aegypti</i> , <i>Aedes albopictus</i>
Filariasis	Nematode	Various <i>Culex</i> spp., <i>Anopheles</i> , <i>Mansonia</i>
Yellow fever	Virus	Mainly <i>A. aegypti</i>
West Nile encephalitis	Virus	Numerous <i>Culex</i> spp.
St. Louis encephalitis	Virus	<i>Culex quinquefasciatus</i> , <i>Culex tarsalis</i> , <i>Culex nigripalpus</i> , others
Western equine encephalitis	Virus	Mainly <i>C. tarsalis</i>
Eastern equine encephalitis	Virus	<i>Ochlerotatus sollicitans</i> , <i>Coquillettidia perturbans</i> , others
La Crosse encephalitis	Virus	Mainly <i>Ochlerotatus triseriatus</i>
Venezuelan equine encephalitis	Virus	<i>Psorophora columbiana</i> , others
Japanese encephalitis	Virus	<i>Culex tritaeniorhynchus</i> , others

humans and animals in Africa. The Gambian form (*Trypanosoma brucei gambiense*) of African trypanosomiasis, or sleeping sickness (see Chapter 92), is transmitted by *Glossina palpalis*, *Glossina fuscipes*, and *Glossina tachinoides*. The East African form (*Trypanosoma brucei rhodesiense*) is primarily transmitted by *Glossina morsitans*, *Glossina swynnertoni*, and *Glossina pallidipes*. Tsetse flies (7 to 13 mm long) are yellow, brown, or black, and fold their wings scissors-like over their back at rest (Fig. 118-29). They superficially resemble honeybees. Contrary to popular belief, people are not the preferred hosts of tsetse flies; these flies feed on a wide variety of mammals and a few reptiles. The effects of their bites are generally self-limited (aside from the disease transmission threat), but

hypersensitive persons may react to the saliva, and subsequent bites produce welts and extensive swelling.

Black flies (insect order Diptera), also known as buffalo gnats or turkey gnats, are small, humpbacked flies that are important as disease vectors and nuisance pests. The causative agent of onchocerciasis, *Onchocerca volvulus*, is transmitted by black flies in tropical areas of Africa and Central America (see Chapter 100). Black flies may attack in swarms, biting viciously. Black flies (2 to 5 mm) are smaller than mosquitoes and are black with a humpbacked appearance. They breed in shallow, fast-flowing streams, mainly in upland regions. *Prosimulium mixtum* is a serious pest of people and animals in much of the United States, as are *Simulium vittatum* and *Simulium venustum*. In Africa, members of the *Simulium damnosum* complex are important vectors of onchocerciasis. Black fly bites may be itchy and slow in healing.

**FIGURE 118-28** Some *Anopheles* mosquitoes appear to have spotted wing patterns. (From Goddard J: Physician's Guide to Arthropods of Medical Importance, 4th ed. Boca Raton, FL, CRC Press, 2002.)

#### HATCHET CELL

**FIGURE 118-29** Adult tsetse fly. (From Yearbook of Agriculture. Washington, DC, U.S. Dept of Agriculture, 1952.)

Occasionally, people experience systemic reactions to black fly bites such as hives, wheezing, and leukocytosis.

## TONGUE WORMS AND LEECHES

### Tongue Worms

Pentastomes (phylum Pentastomida), sometimes also classified as members of the Arthropoda because of their chitinous exoskeleton, are wormlike parasites that are found mainly in the respiratory tracts of carnivorous mammals, reptiles, and birds.<sup>30</sup> Almost half of the genera parasitize snakes. Human parasitism by pentastomes is called pentastomiasis and may occur in the viscera, where nymphs develop in the liver, spleen, lungs, eyes, and other organs, or in the nasopharyngeal area. Nasopharyngeal pentastomiasis involves infestation of the nasal passages, larynx, or eustachian tubes. Most infestations are asymptomatic and only found by radiography, surgery, or autopsy.

The worms vary in color and shape, depending upon the species, but are generally colorless to yellow, ringed organisms with no apparent legs or body regions. The body may be cylindrical or flattened. Females may be up to 130 mm long and 10 mm wide; males are smaller, being up to 30 mm long. On either side of the mouth are two pairs of hollow, fanglike hooks, which can be retracted into grooves like the claws of a cat. Two species account for 99% of the infections in humans.<sup>30,31</sup> The tongue worm, *Linguatula serrata*, which occurs worldwide, is often found in the nasal passages and frontal sinuses of several host animals, but especially dogs (Fig. 118-30). Human infestations may result in discomfort in the throat, paroxysmal coughing, and sneezing. *Armillifer armillatus* (see Fig. 118-30) ordinarily inhabits the respiratory tract of certain snakes in central Africa. In humans, the free-moving larvae may migrate through many tissues and organs. Encysted larvae are often found in the mesenteries.

The life cycle of *Linguatula serrata* is provided as an example of pentastomid biology.<sup>32</sup> Adults are often found in the

nasal passages and frontal sinuses of canines and felines. Eggs are produced and pass out of their host in nasal discharges that are deposited in water or on vegetation. An intermediate host (e.g., rabbit or sheep) swallows contaminated water or vegetation and the eggs hatch into primary larvae, which penetrate the intestinal wall and become lodged in the liver, lungs, or mesenteric nodes. The larvae then pass through two molts resulting in a pupa-like stage. Up to seven more molts may occur before the nymphal stage develops (sometimes called an infective larva). The nymphs then migrate to the abdominal or pleural cavity of the intermediate host where they become encysted. When a definitive host (dog or cat) eats the intermediate host, the nymphs escape rapidly and migrate anteriorly, subsequently clinging to the lining within the host's mouth. From this point they migrate to the nasal cavities where they develop into adults. The adult stage may survive for up to 2 years.

Treatment of pentastomiasis is usually not necessary, but in symptomatic cases surgical removal of the parasites may be needed.<sup>30,31</sup>

### Leeches

Most leeches (annelid class Hirudinea) are bloodsucking parasites that attach themselves to vertebrate hosts, bite through the skin, and suck out a quantity of blood. Other than the nuisance effect of their biting, their medical significance is generally minimal. On feeding, leeches secrete an anticoagulant (hirudin) that aids in securing a full blood meal. Leeches vary in shape from elongated cylindrical to broadly ovoid, and may be black, brightly colored, or mottled; they have muscular suckers at both their anterior and posterior ends. Their dorsal side is convex and the ventral side is flattened. Leeches have external annulation (segments) like other annelids, but differ in having neither setae nor appendages. They are hermaphroditic. Length varies from minute (5 mm long) to giant (45 cm long).

Several different groups or types of leeches occur worldwide. The familiar freshwater leeches parasitize people or animals visiting muddy-bottomed rivers or ponds. This external attachment of leeches is often called external hirudiniasis. The famous medicinal leech, *Hirudo medicinalis*, a freshwater worm about 10 cm long, was often used in the 18th century as a means of bloodletting. Bloodthirsty land leeches inhabit warm moist areas of South America and Southeast Asia. Land or terrestrial leeches commonly live in tropical rain forests where they may be found on stones, shrubs, and leaves. Some leeches attach internally when people drink contaminated water, infesting the upper digestive or respiratory tract. "Horse leeches" may attach inside the pharynx or nasal passages of horses or people drinking water from infested pools or streams in the Middle East or North Africa. The internal leech, *Limnatis nilotica*, is found in southern Europe, northern Africa, and western Asia, where it may become attached to the mucous membranes of the pharynx, nasopharynx, and esophagus. Persons with *L. nilotica* infestation often present with epistaxis, hemoptysis, or hematemesis.

Treatment of leech infestation generally involves only mechanical removal of the worms. This is often done by the victim without medical consultation. However, leech infestation of the nasopharynx, respiratory tract, or esophagus is usually remedied by endoscopic removal.

**FIGURE 118-30** Pentastomids: tongue worm, *Linguatula serrata* (top), and *Armillifer armillatus*, a common species (bottom).

## Distinguishing Tropical Infectious Diseases from Bioterrorism

JUAN P. OLANO  
C. J. PETERS  
DAVID H. WALKER

### MICROORGANISMS AND TOXINS CAUSING TROPICAL DISEASES WITH POTENTIAL USE AS BIOTERROR AGENTS

Bioterrorism can be defined as the intentional use of infectious agents or microbial toxins with the purpose of causing illness and death leading to fear in human populations. The dissemination of infectious agents with the purpose of attacking livestock and agricultural resources has similar motives. Many of the agents that could potentially be used in bioterror (BT) attacks are also responsible for naturally occurring infectious diseases in the tropics. As such, naturally occurring outbreaks must be differentiated from BT attacks for public health, forensic, and security reasons. If a BT attack occurs in tropical underdeveloped countries, owing to their weak public health infrastructure, the public health implications would be even more dramatic than in developed countries. An outbreak of smallpox due to a BT attack would probably require vaccination and mandatory quarantine of millions of people in order to control the outbreak and quell global public unrest. This chapter will concentrate on selected infectious agents that have the potential to be used as bioterror agents in human populations.

The first step in managing the damage from a covert biological dissemination is recognition of the attack and the

organism(s). As in most emerging infections, we predict that in bioterrorist attacks the etiological diagnosis will be made by a clinician or pathologist and the recognition of a bioterrorist event will be through geographical and epidemiological anomalies. We have very limited environmental detection capability at this time, and there are no comprehensive point-of-care diagnostics for most of the high-impact BT agents. Some diseases such as inhalational anthrax or smallpox may be relatively readily recognized by an alert clinician because of their very distinctive presentation in many cases. However, the leading edge of a BT epidemic may arrive on a pathologist's doorstep without prior suspicion. For example, individual cases of pneumonic plague as the earliest harbingers of an attack will presumably present as community-acquired pneumonia and probably die without clinical diagnosis. Given the short window available for successful treatment, the recognition of these earliest cases is paramount. Sartwell<sup>1</sup> has demonstrated empirically that incubation periods follow a log-normal distribution, which results in "front-loading" of cases (Fig. 119-1). Delay in recognizing the epidemic through reliance on syndromic surveillance or other surrogates will likely result in most of the cases of diseases such as plague and tularemia being well into their disease course and perhaps unsalvageable.<sup>2</sup>

Bioterrorist events will enlarge our knowledge of tropical diseases. For example, inhalational anthrax and several viral hemorrhagic fevers (VHF) thought to be transmitted mainly by aerosol<sup>3</sup> are under-represented in naturally occurring case series, and a BT attack would provide an opportunity to answer questions about the underlying host factors

**FIGURE 119-1** Log-normal distribution of incubation periods. (From Sartwell P: The distribution and incubation periods of infectious diseases. *Am J Hyg* 51:310–318, 1950.)

and pathogenesis. Indeed, the extension of the risk population to include children, the elderly, and the immunosuppressed is likely to provide considerable insight into these often-understudied groups. It is also likely that our lack of information about them will challenge our current diagnostic algorithms.

In October 2001, anthrax spores were distributed covertly in the U.S. postal service, leading to 22 cases of human anthrax and billions of dollars spent on controlling the potentially devastating effects of a small inhalational anthrax epidemic.<sup>4,5</sup> This attack was by no means the first intentional attempt to use infectious agents as weapons of terror. Ever since the times of the ancient Greeks and Romans, humans have tried to inflict damage by the use of contagion on other populations.<sup>6,7</sup> Less than 4% of the people or groups responsible for terrorist attacks on human populations take responsibility for their actions.<sup>8</sup> Therefore, the use of biological weapons is ideal to conduct covert attacks. In addition, it has been estimated that to kill the same number of human beings with biological weapons as compared to chemical or nuclear weapons, the cost is far less with biological weapons (\$2/human casualty) compared with chemical (\$2000/human casualty) and nuclear (\$2,000,000/human casualty) weapons.<sup>6</sup> Hypothetical BT attacks would range from an overt attack of a large city with a bomb containing several kilograms of an agent (weaponized bacteria, viruses, or toxins) to discrete or covert intentional release of the infectious agent through a delivery system, such as spray devices, postal service, ventilation ducts, water supplies, and food supply.

Based on transmissibility, severity of morbidity and mortality, and likelihood of use (availability, stability, weaponization), potential BT agents are divided into three categories (Table 119-1). This chapter will concentrate on selected agents from categories A and B and on the diagnostic challenges posed by illnesses caused by such agents.

## EPIDEMIOLOGY

All infectious agents described in Table 119-1 are capable of producing illness under natural circumstances. Therefore, the first challenge is to identify the infectious agent responsible for a certain disease correctly, followed by a thorough epidemiologic and microbiologic analysis of the epidemic or outbreak. In some circumstances, the identification of a BT attack would be obvious. A case of smallpox in any human population is an international emergency that would trigger a massive response of the public health systems around the world. Sophisticated epidemiological investigations would follow in order to characterize the outbreak, identify the source, and possibly label it "intentional." In other cases, the identification of the outbreak as secondary to intentional dissemination of an infectious agent will require the use of sophisticated epidemiological and molecular tools, especially for diseases endemic to the area where the outbreak occurs. The need to use genetic sequences as markers has spawned a new discipline referred to as microbial forensics, sister to phylogenetics and "molecular epidemiology."

Differentiation between natural infections and a biological warfare attack rests firstly on disease patterns given by several epidemiological clues. They include presence of disease outbreaks of the same illness in noncontiguous areas, disease

**Table 119-1 Potential Bioterror Agents**

Categories/Agent	Disease
<b>Category A</b>	
Viruses	
Smallpox	Variola major
Ebola, Marburg, CCHF, RVF, Lassa, Machupo, and Junin viruses	Viral hemorrhagic fevers
Bacteria	
<i>Francisella tularensis</i>	Tularemia
<i>Yersinia pestis</i>	Plague

outbreaks with zoonotic impact, different attack rates in different environments (indoor versus outdoor), presence of large epidemics in small populations, increased number of unexplained deaths, unusually high severity of a disease for a particular pathogen, unusual clinical manifestations owing to route of transmission for a given pathogen, presence of a disease (vector-borne or not) in an area not endemic for that particular disease, multiple epidemics with different diseases in the same population, a case of a disease by an uncommon agent (smallpox, viral hemorrhagic fevers, inhalational anthrax), unusual strains of microorganisms when compared to conventional strains circulating in the same affected areas, and genetically homogenous organisms isolated from different locations.<sup>9,10</sup> These are a few guidelines that could prove helpful when investigating an outbreak, but it has to be kept in mind that the deduction will not be based on any single finding but rather the pattern seen in its totality. First and foremost, the possibility of an attack must be ever in mind, or differentiation of a covert BT attack and a natural outbreak of an infectious disease may not be made. In fact, the outbreak of salmonellosis in Oregon in 1984 was due to a covert attack planned by the Rajneeshee leadership and accompanied by distinctive epidemiological clues. It was not labeled as intentional until somebody came forward with the information leading to the responsible group; as in most of medicine, the unsuspected diagnosis is the easiest to miss.<sup>11</sup>

An increasing number of public health departments are now acquiring the technology necessary to perform syndromic surveillance. This new method of surveillance is based on syndromic disease rates such as respiratory, gastrointestinal, and neurological syndromes or analysis of other health-related activities such as laboratory test requests and results, purchasing

rates for certain pharmaceutical agents, unexplained death rates, and veterinary surveillance.<sup>2,10,11</sup> The purpose of syndromic surveillance is to detect a BT attack as early as possible by analyzing the previously mentioned variables by extracting and analyzing data through computer networks. The rationale behind syndromic surveillance is the nonspecific nature of early signs and symptoms of many of the illnesses caused by BT agents. Examples of proposed syndromes are as follows: gastroenteritis of any apparent infectious etiology, pneumonia with the sudden death of a previously healthy adult, widened mediastinum in a febrile patient, acute neurologic illness with fever, and advancing cranial nerve impairment with weakness.<sup>12</sup> A key component of this system is the continuous analysis of health-care variables to establish thresholds for all variables being analyzed. It is worth mentioning that one of the first flags raised by the human immunodeficiency virus (HIV) pandemic in its early stages in the United States was the increased number of orders for pentamidine from the Centers for Disease Control and Prevention (CDC) to treat several patients in California for *Pneumocystis carinii* pneumonia. As of May 2003, syndromic surveillance systems had been established in approximately 100 sites. One of the best known systems is the so-called Electronic Surveillance System for the Early Notification of Community-based Epidemics (ESSENCE II) being developed by the Johns Hopkins University Applied Biophysics Laboratory.<sup>12</sup> This project is sponsored by the Defense Advanced Research Projects Agency (DARPA) for use in the Department of Defense Global Emerging Infections System. The first system developed (ESSENCE I) is already in use at all U.S. military treatment facilities.<sup>12</sup> ESSENCE II uses the following syndromes for analysis: respiratory, gastrointestinal, fever, dermatological hemorrhagic, dermatological infectious, neurological, and coma.

Factors affecting syndromic surveillance include selection of data sources, definition of syndrome categories, selection of statistical detection thresholds, availability of resources for follow-up, recent experiences with false alarms, and criteria for initiating investigations. It must be emphasized that these systems are experimental and not yet of proven value in managing BT attacks. They are expensive, require follow-up confirmation, have unproven sensitivity and specificity, and ultimately depend on the clinician.<sup>2</sup> They may prove to be more useful in managing an event than in expeditiously detecting one.

Conventional epidemiological investigations are by no means obsolete with the availability of more sophisticated methods to study possible BT attacks. They include the confirmation of an outbreak once it is suspected. Confirmation is based in many cases on laboratory analysis of patients' samples or autopsy material. A case definition is constructed to increase objectivity of the data analyzed and to enable determination of the attack rate. Other variables are included in the analysis, such as time and place, and an epidemiological curve can be constructed.<sup>10</sup> Epidemiological curves are an important tool to analyze epidemics and suggest the mode of transmission and propagation. A point source epidemic curve is classically log-normal in distribution<sup>1</sup> and would suggest a common exposure of a population to an infectious agent. Of course, there can be variations depending on the presence of susceptible subpopulations (e.g., children, immunosuppressed, aged) and on varying doses of the agent. Propagative curves

are more characteristic of highly communicable agents such as smallpox.

A short description of selected category A and B agents follows. All these pathogens are addressed as naturally occurring disease agents in other chapters of this book.

## CATEGORY A

### Bacterial Agents

#### *Bacillus anthracis* (Anthrax)

*B. anthracis* (see Chapter 39) is without a doubt the microorganism that has received the most attention as a BT agent due to its high lethality (inhalational form), ease of propagation, and high environmental stability. Fortunately, the disease is not transmitted from person to person. However, the first three characteristics make it one of the ideal bioweapons.

Anthrax presents in humans as four different clinical syndromes, depending on the portal of entry: cutaneous (the most common form of the disease resulting from contact with infectious animal products), gastrointestinal and oral/oropharyngeal (both secondary to ingestion of contaminated meat), and inhalational (wool sorter's disease), secondary to inhalation of spores from the environment. In the event of a bioterror attack, either overt or covert, the clinical presentation of the patients affected by the attack would be that of inhalational anthrax. This form of anthrax is so rare that a single case of inhalational anthrax should raise immediate suspicion, as dramatically demonstrated during the BT attacks in the fall of 2001.<sup>13–15</sup> During those attacks, 50% of cases were cutaneous anthrax thought to be secondary to handling of anthrax-laced mail envelopes or environmental surface contamination in the presence of minor cutaneous lesions, providing a portal of entry for the spores.<sup>5</sup> An outbreak of inhalational anthrax also took place in Sverdlovsk (former Soviet Union) as a result of an accidental release into the air of *B. anthracis* spores from a facility producing anthrax for the bioweapons program in the USSR.<sup>5,16–18</sup>

Inhalational anthrax should be suspected clinically in any individual presenting with fever and a widened mediastinum on chest radiograph (due to hemorrhagic mediastinitis).<sup>19,20</sup> The incubation period is normally 3 to 5 days, but in some cases it can be as short as 2 days and as long as 60 days depending on inoculum and the time of germination of the spore.<sup>17</sup> Based on research performed on rhesus monkeys, the LD<sub>50</sub> is estimated to be 8000 to 10,000 spores.<sup>21–23</sup> However, as few as 1 to 3 spores may be capable of producing a fatal outcome in approximately 1% of those exposed to these quantities.<sup>24</sup> The initial symptoms are nonspecific and consist of fever, malaise, anorexia, fatigue, and dry cough. These symptoms are followed in 3 to 4 days by an abrupt onset of respiratory insufficiency, stridor, diaphoresis, and cyanosis. The subsequent clinical course is rapid, and patients usually die within 24 to 36 hours after clinical deterioration. Mortality is 100% without antibiotic therapy.<sup>20,25–27</sup> Early diagnosis, aggressive treatment with antimicrobial agents to which the bacteria are susceptible, and aggressive supportive therapy decreased the mortality to 40% in the 2001 attacks.<sup>5</sup> Pathologic studies performed on the Sverdlovsk victims confirmed some of the findings in animal models of inhalational anthrax, such as hemorrhagic lymphadenitis and mediastinitis. However, many

patients also developed hematogenous hemorrhagic pneumonia. Pleural effusions were usually large and frequently led to severe lung atelectasis. In about half of cases, hemorrhagic meningitis developed, leading rapidly to central nervous system (CNS) manifestations terminating in coma and death.<sup>16,28,29</sup>

### *Yersinia pestis* (Plague)

*Y. pestis* (see Chapter 42) is a gram-negative, aerobic, nonsporulating coccobacillus, member of the Enterobacteriaceae with a wide host range, including rodents, felines, and humans.<sup>30</sup> The most important reservoirs are urban rats, and its main vector is the rat flea. In rural epizootics, reservoirs include prairie dogs and squirrels in the United States.<sup>31</sup> *Y. pestis* has been responsible for some of the most devastating pandemics in human history in the preantibiotic era (6th, 14th, and 19th centuries).<sup>32</sup> Public health measures have made this disease a rarity in the United States (around 20 cases/year) and around the world, although approximately 1000 cases are reported to the World Health Organization (WHO) every year (countries reporting plague include Madagascar, Tanzania, and Peru, among others).

Clinical presentation in naturally acquired infections takes five forms, namely bubonic, septicemic, pneumonic, cutaneous, and meningial. The pneumonic form is the most likely presentation in a case of plague due to a BT attack. It is worth mentioning that plague has already been used as a BT agent when Japan dropped thousands of *Y. pestis*-infected fleas over China leading to small outbreaks of bubonic plague in continental China during World War II.<sup>33,34</sup>

The incubation period for pneumonic plague is short, ranging from 2 to 3 days. It is the rarest form in natural infections (1% or less) but has the highest mortality, reaching 100% in untreated patients. The initial presentation is non-specific and consists of cough, fever, and dyspnea. Cough may be productive (bloody, purulent, or watery in the initial phases). This is followed by a rapid clinical course leading to respiratory failure and the patient's demise if not treated with antibiotics early in the course of the disease.<sup>30,31,35</sup>

The factors that led to the severe Manchurian pneumonic plague outbreaks in the early 20th century are unknown, but weather, hygiene, and crowding were important factors. More recent outbreaks worldwide and particularly in the United States have been much smaller and readily controlled. Pneumonic cases are common in the United States, but secondary transmission has been rare in the last 50 years. Modeling of pneumonic transmission using eight small outbreaks to derive the parameters find average of secondary cases per primary case (Ro) to be approximately 1.3 prior to any control measures.<sup>36</sup>

### *Francisella tularensis* (Tularemia)

This is one of the most scientifically neglected microorganisms with BT potential. Tularemia is a zoonotic infection caused by a strictly aerobic, gram-negative, nonsporulating small coccobacillus. Two subspecies are recognized, namely *F. tularensis* subspecies *holarctica* (Jellison type B) and *F. tularensis* subspecies *tularensis* (Jellison type A).<sup>37</sup> Type A is by far the more virulent and is present only in North America.

Of the bacteria with potential as BT agents, *F. tularensis* has by far the widest host range, including wild and domestic animals, humans, fish, reptiles, and birds. Vectors are also numerous and include ticks, fleas, mosquitoes, and biting flies.<sup>37,38</sup> This is an impressive range for any human pathogen.

In contrast to other diseases described in this chapter, tularemia does not have the remarkable history that some of the other pathogens have. In Europe, tularemia was first described in 1532; in the United States, it was first described in 1911 in California in the aftermath of the San Francisco earthquake.<sup>38</sup>

In natural infections, the most common source of infection is a tick bite and manipulation of infected animals such as wild rabbits. Six different clinical syndromes have been described as follows: ulceroglandular, glandular, oculoglandular, pharyngeal, pneumonic, and typhoidal. Marked overlap exists among all these forms, and for practical purposes two syndromes (ulceroglandular and typhoidal) have been proposed.<sup>39–41</sup> As a BT agent, *F. tularensis* will most likely cause a disease with a primary pulmonary component with secondary dissemination (typhoidal/systemic). In natural infections, both ulceroglandular and typhoidal forms can have a hematogenous pulmonary component, although it is more common in typhoidal forms. Pulmonary features include cough, pleural effusions, and multifocal bronchopneumonic infiltrates. If not treated promptly, patients usually develop adult respiratory distress syndrome leading to respiratory insufficiency and the patient's demise. Case-fatality rate approaches 30% if not treated with appropriate antibiotics.<sup>41</sup>

## Viral Agents

### Smallpox Virus (Variola Major)

Smallpox eradication remains the single most important victory in the war against infectious diseases. Smallpox (see Chapter 58) is the only disease so far eradicated from the face of the earth due to human intervention. The WHO declared smallpox eradicated in 1980 after the last case of natural disease was diagnosed in Somalia in 1977,<sup>42</sup> and vaccination ceased around the world, rendering humankind vulnerable to reintroduction of the virus.<sup>43–45</sup> A laboratory accident was responsible for two more cases in 1978 in England. This accident prompted the WHO to restrict the frozen virus to two places in the world: the CDC in Atlanta, Georgia, and the Institute for Polyomyelitis and Viral Encephalitides in Moscow, later moved to NPO VECTOR, Novosibirsk, Russia. However, it is suspected that secret military repositories exist after the fragmentation of the Soviet Union and the subsequent exodus of scientists involved in its bioweapons program (Biopreparat).<sup>46,47</sup> The agent responsible for this disease is an orthopox virus with no known animal reservoir, but high aerosol infectivity, stability, and mortality. Although not a category A agent, monkeypox is responsible for outbreaks in Africa and is the only other member of the orthopox genus capable of producing systemic disease in humans. The clinical disease is potentially indistinguishable from smallpox, where mortality rates in tropical Africa are around 10% to 15%. In May and June 2003, an outbreak of monkeypox occurred in the United States.<sup>48</sup> Thirty-seven infections were laboratory-documented and involved humans exposed to infected prairie dogs that had become infected because of

contact with infected Gambian rats and dormice, two animal species shipped from Africa earlier that year. Infected humans included veterinarians, exotic pet dealers, and pet owners. The clinical spectrum in this outbreak ranged from asymptomatic seroconversions to febrile illness with papulovesicular rash. No deaths were associated with this outbreak. However, phylogenetic analysis of the virus placed it in the West Africa clade as opposed to the Central Africa clade which carries the previously mentioned case-fatality rate of 10% to 15%.

A single case of smallpox would trigger a massive public health response in order to contain the outbreak. An outbreak in Germany in 1970 resulted in 19 cases with 100,000 people vaccinated to contain the infection. In 1972, Yugoslavia underwent an epidemic with a total of 175 cases (35 deaths) and a vaccination program that included 20 million people in order to contain the outbreak and obtain international confidence. Vaccination with the vaccinia virus (a related orthopox virus) is the most effective way to prevent the disease and can be administered up to 4 days after contact with ill patients. Strict quarantine with respiratory isolation for 17 days is also mandatory. The newer generation of antivirals that have been developed after the disease was eradicated has never been tested in human populations, but in vitro data and experiments in animal models of poxvirus disease suggest some antiviral activity for the acyclic nucleoside phosphonates such as cidofovir.<sup>49</sup> The only vaccine available in the United States is Dryvax, and sufficient doses have been manufactured to cover the entire U.S. population. However, newer vaccines that may have fewer side effects are being developed.

The clinical presentation is characteristic. The incubation period ranges from 10 to 12 days. The initial phase is non-specific, common to other viral syndromes, and is characterized by abrupt onset of fever, fatigue, malaise, and headaches. During this prodromal phase in 10% of patients with fair complexion, a discrete erythematous rash appears on the face, forearms, and hands. The typical smallpox rash has a centrifugal distribution (that is, more abundant on the face and extremities than on the trunk and abdomen). An enanthem also develops with presence of oral ulcerations by the time the exanthem appears. Systemic manifestations begin to subside once the rash appears and can reappear with superinfection of skin lesions or superimposed bacterial bronchopneumonia. Progression of the lesions is synchronous (maculopapules, vesicles, pustules). After pustules rupture, scabs form and detach in 2 to 3 weeks, leaving depigmented, scarred areas. This form of the disease, called variola major, is fatal in up to 30% of unvaccinated patients and 3% of vaccinated individuals. Various hemorrhagic forms exist. In some cases, the rash progresses very slowly and hemorrhage develops into the base of the lesions, which remain flat and soft instead of tense, carrying a bad prognosis. In some other cases, the disease is hemorrhagic from the beginning, leading to death 5 to 7 days after the initial symptoms appear (case-fatality rate: 100%). Finally, in some cases, a severe and overwhelming illness is followed by dusky skin lesions; these patients have a large quantity of virus and are extremely dangerous epidemiologically. Previously vaccinated individuals usually develop a milder disease that consists of a mild pre-eruptive phase followed by few skin lesions that appear more superficial, evolve more rapidly, and are not as synchronous as the classical type.<sup>50</sup>

## Viral Hemorrhagic Fevers

Viral hemorrhagic fever (VHF; see Chapter 65) is caused by a heterogeneous group of RNA viruses that belong to several different families. The CDC identified filoviruses (Ebola and Marburg viruses), arenaviruses (Lassa, Junin, Machupo, Guanarito, and Sabia), and bunyaviruses (Crimean-Congo hemorrhagic fever [CCHF] and Rift Valley fever [RVF]).<sup>51–53</sup>

The common denominator in these infections is the increased vascular permeability in the microcirculation leading to hemorrhagic diathesis and systemic manifestations such as pulmonary edema and cerebral edema related to leaky capillaries.<sup>54</sup> These viruses usually have a very narrow geographic range determined by their natural reservoirs and vectors. Humans are accidental hosts. These diseases have caught great public attention due to their high mortality. This, combined with their aerosol infectivity, has led to the use of biosafety level 4 laboratories in their study.

Clinical presentation is usually nonspecific and consists of fever and malaise, followed by signs of increased vascular permeability and circulatory compromise. VHF usually terminates in shock, generalized mucocutaneous hemorrhages, and multi-organ failure. Differences exist among the clinical details and pathogenesis of the different viruses (see Chapter 65 for an overview and the individual chapters for details). For example, VHF due to filoviruses usually have prominent hemorrhagic manifestations and disseminated intravascular coagulation (DIC) as a terminal event. RVF virus leads to liver damage, DIC, and hemorrhagic manifestations in approximately 1% of patients with severe disease. CCHF also behaves like the filoviral infections with prominent hemorrhagic manifestations. Lassa fever has few neurologic or hemorrhagic manifestations. The South American arenaviral hemorrhagic fevers usually have hemorrhagic and neurologic components.

## Diseases Caused by Toxins

Toxins in the context of BT agents are substances of biologic origin that are capable of producing human illness. Toxins are usually proteins synthesized by living bacteria, fungi, or plants. Toxins are generally less dangerous than infectious agents. The most potent biological toxin is that from *Clostridium botulinum* and it is 10-fold or more less lethal than anthrax on a weight basis. Other toxins such as ricin are more than a 1000-fold less toxic than botulinum toxin and sarin is 30-fold less toxic than ricin.

### *Clostridium botulinum* Toxins (Botulism)

There are seven similar toxins produced by seven different serotypes of *C. botulinum* (A to G), all leading to the same clinical manifestations and with the same lethality. The toxins have a molecular weight of approximately 150 kDa and block neurotransmission at the presynaptic level in cholinergic neurons including the neuromuscular junction, leading to progressive palsies of cranial nerves and skeletal muscle. Botulinal toxins are among the most lethal substances known to mankind with LD<sub>50</sub> of 0.001 µg/g of body weight when administered parenterally.<sup>25,55,56</sup> The aerosol route decreases its lethality 80 to 100 times. Both aerosol attacks and contamination of food supplies are potential BT scenarios.

Clinical manifestations consist of progressive bulbar and skeletal paralysis in the absence of fever, including diplopia, dysphagia, blurred vision, ptosis, dysarthria, dysphonia, mydriasis, dry mucosae, and descending paralysis.<sup>25,56</sup> The cause of death in lethal cases is respiratory insufficiency due to paralysis of respiratory muscles. Onset of symptoms is variable and depends on the inoculum, ranging from 24 hours to several days after exposure. Most cases of naturally occurring intoxication are related to consumption of improperly sterilized canned food or ingestion of preserved fish. Rare cases of inhalational botulism were documented in Germany in the early 1960s due to accidental laboratory exposure. The rapid absorption through the respiratory tract may offer a different pathogenesis and it is not known if antitoxin is useful in therapy, although animal models show efficacy in prophylaxis.

## CATEGORY B AGENTS

All the agents in category A are generally recognized as serious threats for causing extensive casualties. Categories B and C are much more heterogeneous. They were considered to provide significant threat potential but there are continuing reassessments.

### Viral Agents

#### Viral Encephalitides

These conditions are caused by the genus *Alphavirus*, family *Togaviridae* (eastern, western, and Venezuelan equine encephalitis [VEE] viruses; see Chapter 74). Natural infections are usually transmitted by mosquitoes, but aerosol transmission is the notorious cause of numerous laboratory infections and is the basis of its historic weaponization.<sup>52,57</sup> Most of these viruses cause systemic illness characterized by fever, myalgias, and prostration.

Clinically apparent involvement of the central nervous system is present in some cases and varies among the different viruses. Eastern equine encephalitis (EEE) is by far the most virulent, leading to case-fatality rates of 50% to 75%, and survivors usually have severe neurologic sequelae.<sup>58,59</sup> VEE, in contrast, leads to CNS manifestations in no more than 4% of cases and almost all VEE infections are symptomatic even in the absence of CNS involvement.<sup>60–62</sup>

### Bacterial Agents

*Rickettsia prowazekii* (Epidemic Typhus)  
and *R. rickettsii* (Rocky Mountain Spotted Fever)

Typhus (see Chapter 51) is another disease that has played a historic role in human populations.<sup>63–66</sup> Millions of people perished in World War I and World War II due to epidemic, louse-borne typhus. Large outbreaks of the disease still occur in tropical regions around the world in areas stricken by war, famine, and poverty. Rocky Mountain spotted fever (RMSF), on the other hand, is transmitted by tick bites and occurs endemically in South and Central America as well as North America. Rickettsiae target the microvascular endothelium leading to leaky capillaries systemically.<sup>67</sup> The main causes of morbidity and mortality are noncardiogenic pulmonary edema and cerebral edema leading to diffuse alveolar damage

and meningoencephalitis. Clinical manifestations are nonspecific and include fever, malaise, headache, myalgias/arthritis, cough, nausea, vomiting, confusion, stupor, and coma in severe cases. Skin rash ranges from maculopapular to petechial, depending on the severity, and is observed in around 90% of patients with RMSF and 2% to 100% of cases of epidemic typhus, depending on the darkness of cutaneous pigmentation. Rickettsiae are remarkably underestimated biothreats as they are highly infectious by low-dose aerosol exposure, possess a stable extracellular form, and are resistant to most empirically administered antibiotics, including  $\beta$ -lactams, aminoglycosides, and macrolides, and are exacerbated by sulfonamides. Case-fatality rates can be as high as 40% to 50% without antibiotic therapy and 3% to 5% with adequate antibiotic coverage. Lethal cases are usually due to delayed diagnosis.<sup>64,65,68</sup>

These rickettsiae are highly infectious by aerosol and are potent BT agents. They are often discounted because of their susceptibility to tetracycline and chloramphenicol. However, the severity of the illness, the exhaustion of antibiotics in the face of a mass attack, and the existence of antibiotic-resistant organisms suggest they are still formidable players.

#### *Coxiella burnetii* (Q Fever)

This gram-negative, obligately intracellular bacterium has a high degree of infectivity (one organism is capable of causing infection by inhalation) and low lethality.<sup>69–72</sup> The distribution of Q fever is worldwide and results from exposure to animals such as sheep, cattle, goats, cats, rabbits, and others. *C. burnetii* has spore-like characteristics that can withstand harsh environmental conditions and be transported by wind to other places. In natural infections, 60% of cases are asymptomatic and are diagnosed by seroconversion. In symptomatic cases, the presentation is nonspecific and includes malaise, fever, myalgias, cough, chills, headaches, anorexia, weight loss, and in some cases pleuritic chest pain. Hepatomegaly and splenomegaly are sometimes observed, although not frequently.

#### *Brucella* spp. (Brucellosis; Other Names: Undulant Fever, Mediterranean Fever, Malta Fever)

Four species of these gram-negative, aerobic, non-spore-forming coccobacilli are pathogenic to humans: *B. abortus*, *B. melitensis*, *B. suis*, and *B. canis* (see Chapter 41). Host ranges include goats and sheep (*B. melitensis*), swine and horses (*B. suis*), cattle, bison, elk, horses (*B. abortus*), and dogs (*B. canis*).

Transmission occurs by exposure to infected animal products (meat, milk). Less common routes of infection are inhalational and cutaneous. The clinical presentation of brucellosis is highly variable, even after inhalational exposure. The clinical spectrum ranges from asymptomatic seroconversion to severe acute systemic disease. Intermediate forms include undulant fever or chronic disease, characterized by presence of *Brucella* in virtually any organ. Acute systemic disease is highly incapacitating with high fever, headache, nausea, vomiting, chills, severe sweating, and, in very severe cases, delirium, coma, and death. Undulant fever is characterized by relapses of fever, weakness, generalized aching, and headache. Chronic infections may have manifestations related to several organ systems such as the gastrointestinal and genitourinary tracts, CNS, joints, and bones.<sup>73–75</sup>

## Food and Waterborne Pathogens

Developing countries with insufficient water treatment and food security are more vulnerable to enteric BT attack. These agents include *Shigella dysenteriae*, *Salmonella* spp., enterohemorrhagic *E. coli*, *Vibrio cholerae*, and *Cryptosporidium parvum*.

*Shigella* and *Salmonella* have in fact already been used as agents of biorevenge or biopolitics in small-scale attacks: one (*Shigella*) in an office setting by a disgruntled employee and one in Oregon by a religious sect that led to nearly 1000 cases of *Salmonella*-related gastroenteritis.<sup>11,76</sup> These agents are indeed ideal for small-scale attacks since large-scale attacks would require contamination of large water supplies which, because of enormous dilution factors and susceptibility of all these agents (except for *C. parvum*) to standard chlorinating procedures, would decrease the number of bacteria to below that required to infect large numbers of people.<sup>69</sup>

Occasional outbreaks of nontyphoidal *Salmonella* and *Shigella* infections occur in the United States. *Shigella* is a highly infectious organism that requires very low numbers ( $10^2$ – $10^3$  organisms) to provoke clinical disease. The illness caused by *Shigella* and enterohemorrhagic *E. coli* is explosive and starts with fever, vomiting, severe abdominal cramping, bloody diarrhea, and systemic manifestations such as hypotension, and circulatory collapse if not treated rapidly. Both microorganisms produce an exotoxin responsible for most of the systemic manifestations associated. A distinct complication, hemolytic uremic syndrome, occurs in a small percentage of cases, being more common in children younger than 10 years of age, leading to renal failure and hemolysis. *Salmonella* is less infectious and less explosive than *Shigella*, and leads to fever, vomiting, diarrhea, abdominal cramping, and in some cases to typhoidal manifestations. Imported cases of *V. cholerae* have been diagnosed in the United States in the past. However, the disease occurs in southern Asia and Latin America as large outbreaks. The clinical illness is characterized by explosive watery diarrhea that leads to rapid dehydration and circulatory collapse.

*C. parvum* infections are characterized by watery diarrhea and abdominal cramping for 2 to 3 weeks. The disease is self-limited except in patients with acquired immunodeficiency syndrome (AIDS) or other conditions of compromise, in whom illness can last for months or years if immune function is not restored. *C. parvum* is resistant to standard chlorine concentrations in water supplies.<sup>77</sup> The largest outbreak in this country occurred in Milwaukee in the early 1990s and was responsible for thousands of cases and increased mortality among those with AIDS.<sup>69,78,79</sup>

## Category B Toxins

This section addresses other toxins considered of potential BT use, such as staphylococcal enterotoxin B (SEB) and ricin toxin (derived from castor beans, which in turn are the fruit of the *Ricinus communis* plant).

### Ricin Toxin (Castor Beans from *Ricinus communis* Plants)

The ricin toxin is composed of two glycoproteins of approximately 66,000 kDa.<sup>80</sup> The toxin inhibits protein synthesis

by blocking elongation factor 2 (EF2) at the ribosomal level. Ricin toxin is not a weapon of mass destruction since its lethal dose in humans is much higher than previously believed. However, the use of the toxin in small BT attacks is possible in the tropics because of its ready availability and relatively easy extraction from the beans. Clinical presentation depends on the route of administration as does the LD<sub>50</sub>. In cases where large amounts of the toxin are ingested, the manifestations include nausea, vomiting, severe abdominal cramping, rectal hemorrhage, and diarrhea. As the clinical course progresses, anuria, mydriasis, severe headaches, and shock supervene leading to the patient's demise in 2 to 3 days. Clinical manifestations usually appear within 10 hours after ingestion of the toxin. Inhalational exposure leads to prominent pulmonary manifestations 8 to 28 hours after exposure and fever, dyspnea, progressive cough, cyanosis, and death. Histologically, there is widespread necrosis of pulmonary parenchyma and pulmonary edema. A single case of parenteral intoxication was documented. A defector from Bulgaria was injected with a pellet containing ricin from a weapon disguised in an umbrella, resulting in local necrosis, regional lymphadenopathy, gastrointestinal hemorrhage, liver necrosis, nephritis, and DIC.<sup>81</sup>

### *Staphylococcus aureus* Enterotoxin B

*Staphylococcus aureus* enterotoxin B (SEB) is a 28-kDa, heat-stable exotoxin produced by certain strains of *S. aureus* and is responsible for food poisoning after ingestion of the preformed exotoxin in improperly handled food. In BT scenarios, exposure can occur either by inhalation or ingestion leading to SEB food poisoning or SEB respiratory syndrome. The toxin is highly incapacitating and not very lethal. The dose that causes symptoms in half of exposed persons and LD<sub>50</sub> differ by a magnitude of 5 log scales for inhalational exposure.<sup>82</sup> Thus, it is thought of as an incapacitating agent.

Incubation time after ingestion is short (4–12 hours) followed by explosive vomiting that persists for several hours. Weaponization of the toxin as an aerosol is possible due to its high stability. Manifestations after inhalation of the SEB are related to the respiratory system and consist of fever, cough, chills, myalgias, chest pain, and pulmonary insufficiency due to alveolar edema. General symptoms and signs are universal and consist of multiorgan failure secondary to a cytokine storm.<sup>25</sup> These toxins are superantigens due to their ability to bind to major histocompatibility complex (MHC) class II molecules on large numbers of lymphocytes and macrophages, leading to a hyperactivation of the immune system and massive cytokine release including interferon-gamma (IFN- $\gamma$ ), tumor necrosis factor-alpha (TNF- $\alpha$ ), interleukin (IL-6), and other mediators such as leukotrienes and histamine.<sup>82</sup>

## DIAGNOSIS

The role of the clinical laboratory in the diagnosis of possible cases related to a BT attack is of utmost importance.<sup>83,84</sup> On the one hand, standard clinical microbiology laboratories will be receiving specimens for diagnostic purposes, and communication with clinicians regarding their suspicions is critical. Certain isolates in the laboratory are not pursued further (*Bacillus* spp. is a classic example) unless specifically requested due to the frequent isolation

of contaminants with similar characteristics. In addition, handling of certain specimens will require added biosafety level requirements due to their infectivity (Table 119-2). Certain samples will have to be shipped to highly specialized laboratories for initial or further work-up. Environmental testing is challenging due to the complexity of the samples to be analyzed.<sup>85,86</sup> This type of testing takes place in highly specialized laboratories and is not undertaken by the standard clinical microbiology laboratory.

## Conventional and Molecular Diagnosis of Potential BT Agents

### General Principles

The bacterial diseases caused by the BT agents outlined in this chapter, with the exception of *C. burnetii* and *Rickettsia* spp., can be diagnosed by standard isolation techniques in clinical microbiology laboratories. Isolation of rickettsiae and the BT viruses requires specialized laboratories with BSL-3 or BSL-4 biocontainment.<sup>87</sup> Serological assays are available for detection of antibodies against all BT agents. However, for many organisms serological assays require the presence of rising antibody titers, and therefore the serologic diagnosis is usually retrospective in nature. For some viral diseases, a reliable diagnosis can be established based on elevation of immunoglobulin M (IgM) titers in the acute phase of the disease.

With the advent of molecular techniques, rapid and sensitive diagnostic tests are becoming available for BT agents during the acute phase of the disease.<sup>88–90</sup> This is of utmost importance in a BT event since identification of the first cases would be critical for a rapid and effective public health response. In addition, treatment and prophylactic measures can also be initiated as quickly as possible. Molecular diagnostic techniques can be applied to potential BT agents in an additional setting: as part of the epidemiological and forensic investigations that a BT attack would immediately trigger. Postmortem diagnosis is also possible by analysis of frozen or paraffin-embedded tissues by immunohistology or nucleic acid–based amplification techniques.

Rapid diagnosis of the initial case (cases) in a BT event requires a high degree of clinical suspicion from the physicians having contact with such patients in the emergency room or outpatient setting. The clinical laboratories would then play a critical role in detecting the suspected agent and/or referring the appropriate specimens to higher level laboratories for specialized testing (Table 119-3).<sup>83,85,91</sup>

Several of the agents discussed in this chapter are zoonotic diseases. Therefore, diagnosis of certain zoonotic diseases in animals may be important in identifying some BT attacks. In such situations, animals could be seen as either direct victims of the attack or as sentinel events in a human outbreak. There are currently efforts to establish a network of laboratories dedicated to diagnosis of veterinary agents.<sup>85</sup>

**Table 119-2 Biosafety in Microbiologic and Biomedical Laboratories**

Level	Definition	Examples
BSL-1	Suitable for work involving well-characterized agents not known to cause disease in healthy adult humans and of minimal potential hazard to laboratory personnel and the environment.	<i>Bacillus subtilis</i> <i>Naegleria gruberi</i> Canine hepatitis virus
BSL-2	Suitable for work involving agents of moderate potential hazard to personnel and the environment. Laboratory personnel have specific training in handling pathogenic agents and are directed by competent scientists; access to the laboratory is limited when work is being conducted; extreme precautions are taken with contaminated sharp items; and certain procedures in which infectious aerosols or splashes may be created are conducted in biological safety cabinets or other physical containment equipment.	Measles virus <i>Salmonella</i> spp. <i>Toxoplasma</i> spp. Hepatitis B virus
BSL-3	Suitable for work with infectious agents which may cause serious or potentially lethal disease as a result of exposure by the inhalation route. In addition to the requirements described for work in BSL-2 environment, all procedures are conducted within biological safety cabinets, or other physical containment devices, and by personnel wearing appropriate personal protective clothing and equipment. Laboratory should be located in a separate building or an isolated zone within a building. Laboratories are equipped with double door entry, directional inward flow, and single-pass air.	<i>Coxiella burnetii</i> <i>Rickettsia</i> spp. <i>M. tuberculosis</i> Alphaviruses
BSL-4	Required for work with dangerous and exotic agents that pose a high individual risk of aerosol-transmitted laboratory infections and life-threatening disease. Members of the laboratory staff have specific and thorough training in handling extremely hazardous infectious agents. They are supervised by competent scientists who are trained and experienced in working with these agents. Access to the laboratory is strictly controlled by the laboratory director. The facility is either in a separate building or in a controlled area within a building, which is completely isolated from all other areas of the building. All activities are confined to Class III biological safety cabinets, or Class II biological safety cabinets used with one-piece positive pressure personnel suits ventilated by a life support system. The Biosafety Level 4 laboratory has special engineering and design features to prevent microorganisms from being disseminated into the environment.	Filoviruses Arenaviruses

**Table 119-3 Laboratory Response Network for Bioterrorist Attacks**

Level	Functions
A	Community level laboratories that should recognize the clues of a possible bioterrorist agent and be able to package samples and ship them for confirmation at the upper-level laboratories.
B	State and county public health laboratories with capacity to work with BSL-2 and some with BSL-3 agents. Capable of isolation of some of the agents, presumptive level testing, and antibiotic susceptibility profiles.
C	Greater BSL-3 capabilities than level B and molecular testing capabilities for rapid identification.
D	Highest level of containment (BSL-4) for isolation and identification of highly pathogenic viruses.

## Diagnosis of Specific BT Agents

### *Bacillus anthracis*

The diagnosis of inhalational anthrax is based on isolation and identification of *B. anthracis* from a clinical specimen collected from an ill patient. In cases of inhalational anthrax, samples of sputum, blood, or cerebrospinal fluid (CSF) may yield growth of the agent. Demonstration of *B. anthracis* from nasal swabs has more epidemiological and prophylactic implications than clinical importance. Standard diagnostic techniques are based on visualization and isolation in the clinical microbiology laboratory and serological demonstration of antibodies against *B. anthracis*.<sup>92–96</sup>

Visualization of *B. anthracis* from clinical specimens (blood cultures, CSF, and cutaneous lesions) by Gram stains is not difficult. *B. anthracis* appears as large gram-positive, spore-forming rods with a bamboo appearance. Isolation is achieved by inoculating standard sheep blood agar plates, and colonies appear as small, gray-white, nonhemolytic colonies. A selective medium (polymyxin-lysozyme-EDTA-thallos acetate agar) is available mostly for environmental samples and inhibits the growth of other *Bacillus* spp., such as *B. cereus*. Growth is rapid (24–48 hours).<sup>93</sup> Confirmatory tests include  $\gamma$ -phage lysis, detection of specific cell wall and capsular antigens, and polymerase chain reaction (PCR) amplification of DNA followed by sequencing.<sup>90</sup>

Serological tests available for clinical diagnosis are based on detection of antibodies directed against protective antigen (PA). Cross-reactive antibodies decrease the specificity of this test. Assays based on toxin detection are available in specialized centers and are based on capture of anthrax toxins by using antibodies. Antibody-coated immunomagnetic beads are then analyzed by electrochemiluminescence technology. The analytical sensitivity of this technique for detection of anthrax toxin is at the picogram to femtogram level ( $10^{-12}$  to  $10^{-15}$ ).<sup>97,98</sup> Immunoliposomal technology

combined with real-time PCR (for a DNA reporter sequence) is also in the early stages of development for several toxins (ricin, cholera, and botulinum) and appears promising with analytical sensitivity in the attomolar to zeptomolar ( $10^{-18}$  to  $10^{-21}$ ) range for cholera toxin.<sup>99</sup> The specificity of this assay is given by the toxin-capturing antibody.

Nucleic acid amplification techniques (PCR) are also available both in standard format and real-time format. Extraction of DNA from spores is challenging and requires modification of DNA extraction protocols in order to facilitate release of DNA from spores or induction of germination prior to DNA extraction.<sup>90</sup> Real-time PCR tests have been developed by Applied Biosystems (TaqMan 5' nuclease assay) and Roche Applied Science (LightCycler).<sup>100–102</sup> The analytical sensitivity of both techniques is extremely high, and testing times have been decreased to 1 to 2 hours. Portable PCR instruments are being developed for rapid deployment to the field.<sup>103</sup> Examples include the rugged advanced pathogen identification device (RAPID),<sup>100</sup> the Smartcycler (Cepheid, CA),<sup>101</sup> and the miniature analytical thermal cycler instrument (MATCI) developed by the Department of Energy's Lawrence Livermore National Laboratory.<sup>104</sup> This instrument later evolved into the advanced nucleic acid analyzer (ANAA) and handheld advanced nucleic acid analyzer (HANAA).<sup>105</sup>

Molecular subtyping of *B. anthracis* is also possible by using the 16S ribosomal RNA (rRNA) subunit gene, multiple-locus variable number tandem repeat analysis of eight genetic loci, and amplified fragment length polymorphism (AFLP) techniques.<sup>106,107</sup>

Environmental testing also plays a role in the investigation of a BT event. In this setting, detection of *B. anthracis* relies heavily on molecular techniques for confirmation of potentially contaminated samples (e.g., surfaces, air).<sup>108,109</sup>

Postmortem diagnosis is also possible by using Gram stains on paraffin-based tissues or immunohistochemical procedures using polyclonal or monoclonal antibodies against various anthrax antigens.

### *Yersinia pestis*

Diagnosis of *Y. pestis* is based on demonstration of the bacillus in blood or sputa from patients. Standard diagnostic techniques in the laboratory include visualization of gram-negative coccobacilli, which by Giemsa, Wright, or Wayson stains reveal a "safety pin" appearance. Isolation is performed in blood and McConkey agar plates on which colonies appear as nonlactose fermentors. The organisms are identified preliminarily by direct immunofluorescent assay with *Y. pestis*-specific antibodies, with final identification based on biochemical profiles in clinical microbiology laboratories.<sup>110</sup>

Molecular diagnostic techniques based on real-time PCR have become available in recent years and involve detection of *Y. pestis* genes such as plasminogen activator (*pla*), genes coding for the Yop proteins and the capsular F1 antigen, and the 23S rRNA gene, which allows distinction from other *Yersinia* spp.<sup>111–113</sup> Assays have been developed to detect resistance to particular antibiotics. The importance of these diagnostic techniques in a disease such as plague is evident. The log-normal epidemic curve with a narrow dispersion of the incubation periods (see Fig. 119-1) and the short interval for successful antibiotic therapy mandate

recognition of the earliest cases if the bulk of the exposed are to be saved. Molecular subtyping of *Y. pestis* is also possible by analyzing polymorphic sites in order to identify the origin of strains in the event of a BT attack.

### *Francisella tularensis*

Diagnosis is made in the clinical laboratory by demonstration of the microorganisms in secretions (sputa, exudates) by direct immunofluorescence or immunohistochemically in biopsy specimens. Isolation in the clinical laboratory may be achieved by using regular blood agar plates, posing a risk to laboratory personnel not employing BSL-3 facilities and procedures.

The procedure for isolation of *F. tularensis* in the laboratory is very similar to that described for *Y. pestis*. Final identification in the clinical laboratory is based on the biochemical profile.<sup>114</sup> Molecular diagnostic techniques are based on PCR detection of *F. tularensis* by using primers for different genes such as outer membrane protein (*Fop*) or *tul4* and real-time detection systems.<sup>90,115,116</sup>

### Smallpox Virus

Diagnosis of variola major is suggested by its clinical presentation and the visualization of Guarnieri bodies in skin biopsy samples. Preliminary confirmation requires visualization of the typical brick-shaped orthopox virus by electron microscopy, followed by isolation from clinical specimens and accurate molecular identification to differentiate it from the morphologically (and sometimes clinically) similar monkeypox virus. Confirmation of this diagnosis is performed only under BSL-4 containment facilities at the CDC.<sup>47</sup>

Molecular techniques are based on PCR amplification using real-time or standard technology followed by sequencing or use of restriction fragment length polymorphism (RFLP) for accurate identification.<sup>117</sup> Technologies so far developed for smallpox molecular testing include Taqman- and LightCycler-based assays with primers designed for the hemagglutinin gene and A-type inclusion body proteins.<sup>118–121</sup>

Sequencing of the smallpox genome has been completed for some Asian strains of variola major and one of variola minor. Other strains are being sequenced and will provide more information for probe design and treatment targets.<sup>90</sup>

### Viral Hemorrhagic Fevers

Diagnosis of these diseases is performed in highly specialized centers in the United States because special isolation procedures and highly contained laboratories are required.

Initial diagnosis of these diseases is suspected on clinical and epidemiologic grounds. Laboratory diagnosis involves isolation, electron microscopy, and serological assays. Immunohistochemical detection of hemorrhagic fever viral antigens in paraffin-embedded tissues is also performed in highly specialized centers such as the CDC.<sup>122–126</sup>

Molecular diagnostic techniques have also improved dramatically during the last few years. Serum or blood is the most common specimen used for reverse transcriptase–PCR amplification of viral nucleic acids. Both standard and real-time techniques are available.

Design of primers for this heterogeneous group of RNA viruses that are highly variable is one of the limitations.<sup>90</sup> Therefore, multiplex PCR techniques are required to detect as many targets as possible in a single assay.<sup>127,128</sup> Real-time PCR based on detection of the target sequence using fluorescent probes therefore limits the number of targets that can be identified because of the limited wavelength range for fluorescent applications (usually only four different wavelengths can be detected at the same time).<sup>128–130</sup> The use of microchips containing several thousands of oligonucleotides from all viruses known to be pathogenic to humans is an encouraging development. In fact, the rapid identification and characterization of the novel human coronavirus responsible for the SARS outbreak in 2003 is an excellent example of the power of hybridization-based microchips.

The creation of an automated and easily deployable instrument capable of detecting all possible potential BT agents based on highly sensitive techniques such as electrochemoluminescence (ECL) or PCR would be ideal. The nonspecific nature of presenting symptoms is a major problem with several of the agents. The rapid recruitment of cases into the infected cohort requires that an early diagnosis of the epidemic be established, particularly for organisms such as *Y. pestis* in which there is only a short window for successful treatment. In fact, such projects are already in the making. An example of this system is the Automated Biological Agent Testing System (ABATS) that combines the techniques mentioned previously.<sup>86</sup> The system is the result of integrating several commercially available technologies into a single automated and robotized instrument for detection of viruses, bacteria, and parasites considered potential BT agents. The technologies incorporated into this “super system” include automated specimen preparation (both nucleic acid–based and protein–based such as immunodiagnostics), thermocyclers for PCR detection, chemiluminescent detectors for immunobased assays, sequencers, and software programs for sequence analysis.

### Category B Agents

*Rickettsia prowazekii* (Epidemic Typhus) and  
*R. rickettsii* (Rocky Mountain Spotted Fever)

Diagnosis of these infections in the clinical microbiology laboratory currently rests on the identification of antibodies in serum during the acute and convalescent period in order to demonstrate seroconversion or rising titers. The diagnosis is therefore retrospective.<sup>131,132</sup> Detection of rickettsial DNA from blood or skin samples during the acute phase of the disease is possible via PCR assays. However, these assays are not standardized and are not commercially available. Primers have been designed for amplification of several rickettsial genes including citrate synthase, 17-kDa protein gene, *OmpA*, and *OmpB*.<sup>132–136</sup> The clinical sensitivity and specificity of standard or real-time PCR techniques have not been determined. Most likely real-time PCR is superior due to the higher analytical sensitivity of this technique and low risk of sample contamination with DNA amplicons when compared to standard PCR amplification methods.

Isolation of rickettsiae from clinical specimens is performed in very few specialized laboratories in the nation

and requires the use of cell monolayers, embryonated eggs, or animals. Detection of rickettsial antigens or whole bacteria in blood specimens is theoretically possible by using ultrasensitive methods, but such assays are currently only in the early phases of development. Immunohistochemical detection of rickettsiae in paraffin-embedded tissue has also been applied to tissue samples obtained pre- or postmortem.<sup>137–139</sup>

*Salmonella* spp., *Shigella dysenteriae*, *Vibrio cholerae*, and *Cryptosporidium parvum* (Acute Enteric Syndromes)

Diagnosis of *Salmonella*, *Shigella*, and *Vibrio* infections is based on isolation of the offending agent on standard microbiological media in the clinical laboratory, followed by specialized confirmatory tests to identify the specific serotype involved.<sup>140</sup> Diagnosis of *C. parvum* is based on visual identification of the protozoan in fecal specimens by using modified trichrome stain.<sup>140</sup>

*Coxiella burnetii* (Q Fever)

The diagnosis rests on serological demonstration of antibodies by immunofluorescent assay (IFA) or enzyme-linked immunosorbent assay (ELISA). Antibodies remain elevated for years after the acute infection, and therefore a fourfold rise in titers is the gold standard for diagnosis. PCR detection of *C. burnetii* DNA from blood or tissues also yields a diagnosis of Q fever.<sup>88</sup>

*Brucella* spp.

Diagnosis of brucellosis requires a high degree of clinical suspicion due to the protean manifestations related to this disease. Laboratory diagnosis is based on isolation of the microorganism from blood, bone marrow, or other tissue samples. Isolation is not easy due to the slow-growth of *Brucella* spp. Colonies usually appear after 4 to 6 weeks, and therefore communication with the clinical laboratory is important so that appropriate media will be used and the cultures will be held long enough for colonies to be detected.<sup>90</sup> Serologic assays for demonstration of rising antibody titers are available, although the diagnosis is retrospective. PCR detection is promising, but it is not standardized.<sup>141–143</sup>

Alphaviruses (Encephalitic Syndromes: Venezuelan, Eastern, and Western Equine Encephalomyelitis)

Diagnosis is based on isolation of the virus from serum or brain (postmortem specimens) in a BSL-3 environment. PCR detection of viral sequences is also possible. Serologic diagnosis is based on demonstration of antibodies in acute and convalescent sera.<sup>144–146</sup>

*Botulinum* Toxins

The diagnosis of botulism relies heavily on clinical parameters. An afebrile patient with signs and symptoms of progressive bulbar palsies and descending neuromuscular paralysis is highly suspected of having botulism. Demonstration of the toxin in cases of botulism due to

ingestion of contaminated food is made from gastric samples, feces, blood, and urine. However, detection of minute amounts of toxin (and contacts with samples from cases may prove fatal due to the toxin's potency) would be difficult by current immunoassay systems such as ELISA platforms.<sup>146</sup> Detection techniques based on electrochemiluminescence and immunoliposomes are currently under development.<sup>99,147</sup> PCR assays can be performed in cases of ingestion of contaminated food in order to detect the genetic material present in *C. botulinum*. If weaponized toxin is used in the absence of *C. botulinum* organisms, detection of the genetic material would be difficult and would rely on the presence of residual DNA after toxin purification procedures. If inhalational botulism is suspected, respiratory secretions and nasal swabs should be obtained as early as possible. Postmortem samples of liver and spleen can be used for detection of botulinum toxins.

Ricin Toxin

Diagnosis is also based on clinical presentation and requires a high index of suspicion due to the nonspecific nature of the signs and symptoms. Laboratory diagnosis rests on detection of the toxin in body fluids by immunoassays (capture ELISA and IgG ELISA).<sup>146</sup> A new generation of tests using more sensitive detection methods is under development (see preceding discussion).

Staphylococcal Enterotoxin B

Diagnosis is also suspected on clinical grounds and confirmed by demonstration of the toxin in nasal swabs early in the disease process, feces, and, in fatal cases, from kidney and lung tissue. Serum can be analyzed by ELISA, and PCR can be performed for detection of toxin genes of *S. aureus* if present.<sup>146</sup>

# Health Advice for International Travel

JAY S. KEYSTONE  
ROBERT STEFFEN  
PHYLLIS E. KOZARSKY

## INTRODUCTION

International travel has become increasingly common as travelers search out exotic vacation destinations or conduct business, government, or missionary activities in remote areas of the world. It is estimated that there are approximately 700 million international tourist arrivals alone each year, and world tourism organization statistics show that travel from industrialized areas to developing countries until 2001 increased dramatically. In 1999, more than 35 million North Americans, 25 million Europeans, 11 million Japanese, and 3 million Australians and New Zealanders traveled to developing areas.<sup>1</sup> Unfortunately, studies show that between 50% and 75% of short-term travelers to the tropics or subtropics report some health impairment, usually due to an infectious agent.<sup>2-4</sup>

Although infectious diseases contribute substantially to morbidity, they account for only 1% to 4% of deaths among travelers.<sup>5-9</sup> Cardiovascular disease and injuries are the most frequent causes of death among travelers, accounting for approximately 50% and 22% of deaths, respectively. If one excludes mortality due to cardiovascular disease and pre-existing illness, motor vehicle accidents account for more than 40% of the remaining causes of death. Age-specific rates of mortality due to cardiovascular disease are similar to those of nontravelers, whereas injury deaths, the majority from motor vehicle accidents and drowning, are several times higher among travelers.<sup>9</sup>

The provision of health recommendations for international travelers is based on individual risk assessment and requirements (e.g., immunizations) according to the countries on the itinerary of the traveler. As shown in Figure 120-1, the estimated monthly prevalence of health problems includes such preventable diseases as travelers' diarrhea (in 30% to 80%, depending on destination), malaria (in 2.5% of travelers to West Africa without chemoprophylaxis), hepatitis A (0.3%), and typhoid fever (in 0.03% of travelers to India, West Africa, or Peru). The risk of acquiring illness depends on the area of the world visited, the length of stay, activities and location of travel within these areas, and the underlying health of the traveler. For example, a business traveler who spends 1 week in an urban center of Southeast Asia needs much less detailed advice and fewer immunizations than the backpacker who plans to spend 6 months trekking across rural Africa. In addition, an increasingly important

but previously unrecognized group at particularly high risk for travel-related problems are individuals returning to visit friends and relatives (referred to as VFRs) in their countries of origin.<sup>10</sup> VFRs currently account for approximately 40% of international travelers from North America.<sup>11</sup> Therefore, it is essential that the health advisor know

- the country of origin
- the itinerary
- the length of stay in each country
- whether travel will be rural or urban
- the style of travel (e.g., first-class hotels vs. local homes)
- the reason for travel
- whether the traveler has any health problems, allergies, or previous immunizations
- in the case of a female traveler, whether or not she is planning pregnancy or is pregnant

## IMMUNIZATIONS

### General Considerations

Immunizations for international travel can be categorized as routine childhood and adult immunizations (e.g., diphtheria, tetanus, poliomyelitis, measles, mumps, and rubella); required—those needed to cross international borders as required by international health regulations (e.g., yellow fever and meningococcal); and recommended according to risk of illness (e.g., hepatitis A, typhoid, and rabies).

Before discussing the rationale for various immunizations, it is important to review several practical issues regarding vaccine administration:

1. Interrupted multidose schedules: Regardless of the duration of interruption of a schedule, there is no need to restart a primary series of immunizations. It is sufficient to continue where the series was interrupted.
2. Simultaneous administration of vaccines: Inactivated and live vaccines can be administered simultaneously at separate sites. Theoretically, live vaccines should be administered simultaneously or 30 days apart because of possible impairment of the immune response. Since live virus vaccines can interfere with an individual's response to tuberculin testing, the test should be done on the day of immunization or 4 to 6 weeks later.
3. Immune globulin administration: When certain live attenuated vaccines are given with immune globulin, the antibody response may be diminished. This caveat does not apply to yellow fever vaccine. However, the measles-mumps-rubella (MMR) vaccine and its component vaccines should be delayed after immune globulin administration; the duration of delay is dependent on the purpose for which the immune globulin was administered—for example, 3, 4, and 5 months for hepatitis A, rabies, and measles or varicella prophylaxis, respectively.
4. Hypersensitivity to vaccine components: The most common animal protein allergen is egg protein in vaccines prepared from embryonated chicken eggs (e.g., influenza and yellow fever vaccines) or gelatin (e.g., MMR). Screening people by asking whether they can eat eggs without an allergic reaction is a good way to identify those who may be at risk from embryonated

**FIGURE 120-1** Incidence rate per month of health problems during stays in developing countries. ETEC, enterotoxigenic *Escherichia coli*. (Adapted from Cook GC: Manson's Tropical Diseases, 20th ed. Philadelphia, WB Saunders.)

chicken egg vaccines. Preservatives such as thimerosal or trace amounts of antibiotics such as neomycin may cause a hypersensitivity reaction to a vaccine; however, thimerosal is being removed from these products. The package insert should be reviewed carefully if the traveler gives a history of hypersensitivity.

5. Altered immunocompetence: Inactivated vaccines pose no danger to the immunocompromised host, although the immune response to these vaccines may be suboptimal. Since virus replication after administration of live attenuated vaccines can be enhanced in the immunocompromised host, live vaccines generally should be avoided in such people. Exceptions apply in the recommendations for yellow fever and measles immunization in people with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS). Immunization of the HIV-infected traveler is summarized in Table 120-1.
6. Pregnancy: Live vaccines are contraindicated during pregnancy, except for yellow fever vaccine in those at very high risk. An inactivated vaccine, Japanese encephalitis vaccine, theoretically poses a risk to the pregnant woman<sup>12</sup>; however, it should be administered in situations in which the risk of infection is significant. Breast-feeding is not a contraindication to vaccine administration. Detailed travel health recommendations for pregnant women and children may be found in the Centers for Disease Control and Prevention (CDC) publication Health Information for International Travel<sup>13</sup>

and others.<sup>14-17</sup> The CDC guide, published biennially, also provides a complete discussion of the general principles and specific country-by-country requirements for immunizations.

7. Infants: Infants may be started on immunization as early as at birth for hepatitis B and IPV, at 4 and 6 weeks for diphtheria-tetanus-acellular pertussis (DTP) and *Haemophilus influenzae* b (Hib) vaccines, respectively, and at 6 months for measles (followed by full recommended schedules).

### Routine Immunizations

Travel is an excellent opportunity to update a person's "childhood" immunizations, such as DTP, MMR, polio, Hib, hepatitis B, and varicella. Administration of pneumococcal and influenza vaccines should also be considered. If a traveler is already immune to any of these infections, immunization will not lead to an increase in vaccine-related adverse reactions. See Table 120-2 for vaccine schedules, indications, precautions, contraindications, and side effects. Immunizations are discussed in the Guide for Adult Immunization,<sup>18</sup> in the recommendations of the Advisory Committee on Immunization Practices,<sup>19</sup> and in the Canadian Immunization Guide.<sup>20</sup>

### Required Immunizations

Yellow fever vaccination may be a legal requirement for all travelers wanting to enter countries where the disease is

**Table 120-1 Summary of Immunization Safety in the Pregnant or HIV-Infected Traveler**

Vaccine	Safety in Pregnancy	Safety with AIDS
<b>Bacterial</b>		
Tetanus–diphtheria	Yes*	Yes
Pneumococcal	Yes†	Yes
Meningococcal		
Typhoid		
Killed polysaccharide	Yes	Yes
Live attenuated	Unknown‡	Unknown‡
<i>Haemophilus influenzae</i> b	Yes†	Yes
Conjugate	No	Yes
Cholera (injectable)	Yes	Yes
BCG	Unknown§	No
<b>Viral</b>		
Polio		
Inactivated (eIPV)	Yes	Yes
Live attenuated	No	No
Yellow fever	Yes§	No§
Measles–mumps–rubella	No	Yes†
Varicella		
Influenza		
Rabies	Yes	Yes
Japanese B encephalitis	Unknown‡	Unknown‡
Hepatitis A	Yes†	Yes
Hepatitis B	Yes	Yes
Immune globulin	Yes	Yes

BCG, bacilli Calmette–Guérin; eIPV, enhanced potency inactivated polio virus.

\*Should ideally wait until after the first trimester.

†Probably safe but has not been studied conclusively.

‡Safety is unknown, and vaccination should be avoided until further study.

§Should generally be avoided but may be given with high-risk exposure.

Data from Hill DR: Immunizations for foreign travel. *Yale J Biol Med* 16:293–315, 1992; and Hill DR, Pearson RD: Health advice for international travel. In Reese RE, Betts RF (eds): *A Practical Approach to Infectious Diseases*, Boston, Little, Brown, 1996, pp 812–845. See Table 120-2 4th ed for full details.

present, and it may be necessary for those transiting countries either known or thought to harbor yellow fever virus. Yellow fever has been making a comeback in recent years, and as a result fatalities in tourists have been documented.<sup>21</sup> The risk of yellow fever is highest in sub-Saharan Africa, estimated to be as high at 1:250 per 2-week stay during an epidemic and 1:2500 between epidemics. The risk in South America is considerably less—approximately 1:25,000 for a 2-week exposure.<sup>22</sup>

The vaccine must be approved by the World Health Organization (WHO) and must be administered at an approved yellow fever vaccination center.<sup>23</sup> Vaccinees should receive an International Certificate of Vaccination, which is signed and stamped. The vaccine is recommended for all travelers passing through or living in countries in tropical Africa and South America where yellow fever is officially reported or for those traveling to areas within yellow fever endemic zones. These areas are specified on the WHO and CDC travel health web sites: [www.who.int/ith](http://www.who.int/ith) and [www.cdc.gov/travel](http://www.cdc.gov/travel). However, a risk:benefit analysis concerning use of the vaccine is important, particularly among senior travelers, because of the risk of severe adverse reactions that may occur in 1:200,000

to 1:300,000 vaccinees overall and in 1:50,000 of the elderly.<sup>22–24</sup>

Although officially no country requires administration of cholera vaccine for entry, documentation of vaccination has been known to be requested by officials at few remote borders. The risk of cholera among travelers is extremely low (1:500,000 travelers).<sup>25</sup> The phenol-killed whole-cell cholera vaccine is no longer available. Newer vaccines (oral B-subunit whole-cell cholera vaccine) provide approximately 85% protection for approximately 6 months, but they are not effective against the serotype O139, which has been spreading throughout Asia.<sup>26–28</sup> The vaccine is available in Canada and in some European countries but not in the United States. It is recommended only for health-care workers, backpackers, and other volunteers working in highly endemic areas (e.g., refugee camps) who are likely to be exposed to infection.

After a large outbreak of meningococcal meningitis during the Haj in Saudi Arabia in 1987, national public health authorities required pilgrims to the Haj and Umra to be immunized with the A serotype.<sup>29</sup> However, when another outbreak occurred in 1999, this one due to the W-135 serotype, the quadrivalent vaccine (containing A, C, Y, and W-135 serotypes) was made a requirement for all pilgrims,<sup>30</sup> and a new conjugate quadrivalent vaccine has recently become available.

## Recommended Immunization

Hepatitis A is one of the most frequent vaccine-preventable infections of travelers. In one study, the incidence of symptomatic infection during a 1-month stay in a developing country ranged from 3 to 6 cases per 1000 in resort areas but increased to 20 per 1000 for those who strayed from the usual tourist routes.<sup>31,32</sup> Recent data suggest that the incidence may be lower at 1:3000 to 1:10,000 per month of stay in the developing world.<sup>33–36</sup> Mortality from hepatitis A infection increases with age and reaches 2.1% in those older than age 40 years and almost 3% by the age of 50.<sup>37</sup> Although most infants and young children are asymptomatic when infected, they do pose a health risk to others due to the ease of fecal-oral spread of this virus.<sup>37,38</sup> Hepatitis A vaccination is recommended for all international travelers to developing countries, although some public health authorities believe that hepatitis A vaccine should be administered more widely, even for those not traveling to endemic areas.

Available hepatitis A vaccines are highly efficacious, with seroconversion rates of almost 100% by the second dose.<sup>39,40</sup> Within 2 weeks of the first dose, between 70% and 85% of vaccinees will have protective levels of antibody, but most experts believe that protection against symptomatic infection is granted even if that dose is given on the day of departure. Simultaneous administration of immune serum globulin may reduce peak antibody levels; however, this has not been shown to interfere with long-term protection.<sup>41</sup> Thus, most national vaccination advisory committees do not recommend simultaneous administration of immune globulin with hepatitis A vaccine even with imminent travel. An expert panel that reviewed the data on vaccine efficacy concluded that hepatitis A vaccines will provide lifetime immunity.<sup>42</sup>

The monthly incidence of hepatitis B infection, both symptomatic and asymptomatic, is 80 to 240 cases per 100,000 for long-stay overseas workers who are at considerable risk of

Table 120-2 Immunizations for International Travel

Vaccine	Type	Schedule	Indications	Precautions and Contraindications	Side Effects
Routine Diphtheria–tetanus– pertussis, <i>Haemophilus</i> <i>influenzae</i> b Influenza	Inactivated whole and split influenza A and B viruses	See references 13, 14	Those at increased risk of complications from influenza; healthy adults >65 yr	H—eggs P—safety unknown	<35% mild local reactions; occasional systemic reactions; rare allergic reactions
